Foreword

The eighth edition of *Scott-Brown* signals the beginning of a new and exciting era for ear, nose and throat surgeons, and also the end of 10 years of very hard work undertaken by John Watkinson and Ray Clarke, the Editors-in-Chief, their team of subeditors and, not least, the publishers. Whatever subspeciality the current generation of trainees decides to follow, they will all have to read and refer to *Scott-Brown* in order to complete their education and gain accreditation. It will be a constant companion and guide throughout their professional lives.

When asked to write the foreword for this edition, I was immediately reminded that I had read John Ballantyne and John Groves's third edition as a trainee, bought the fourth edition as a senior registrar, written chapters for Alan Kerr and Philip Stell in the fifth edition, edited the *Basic science* volume of the fifth edition and was ultimately Editor-in-Chief of the seventh edition. As each edition takes about 10 years to produce, that makes me very old indeed. John and Ray have one final task as Editors-in-Chief: to recommend their successors to the publishers. That was made easy for me as both of them had proved themselves more than capable with the previous edition, and the eighth edition is now their masterpiece. They can enjoy the next 10 years as thousands of surgeons worldwide recognize and thank them for their industry.

This edition reflects the continued expansion of our speciality into fields that Scott-Brown himself could never have imagined. It lays the groundwork for the current generation to make their contribution that will, no doubt, be prompted by technological developments, an evidence base of what is wise and what is not, together with the experience gained by teamwork with other clinicians in today's multidisciplinary approach to patient care.

Simply looking at the table of contents it is clear to see that our role in endocrine surgery has increased dramatically over the last 10 years. The thyroid and parathyroids now account for 30 chapters. How would Scott-Brown have viewed that when the tonsils and adenoids justify just one chapter each, and the sore throat has a mere passing reference? Times have certainly changed and ENT surgery has grown up. We have reflected on our past practices, and the evidence base for our management protocols that was emphasized in the previous edition of *Scott-Brown* has been taken to heart.

I hope that this edition will find its way into every medical library in the world and onto every ENT surgeon's bookshelf. It will serve and guide surgeons throughout the English-speaking world, whether they live in high- or low-income countries. It is said that the tragedy of getting old is that we feel young. Reading these volumes makes me wish that I had my time all over again.

Michael Gleeson

Taylor & Francis

Preface

When we were asked to head up the editorial team for this, the eighth edition of *Scott-Brown*, we were mindful of Michael Gleeson's towering achievement in bringing the seventh edition to fruition. Michael delivered a much-loved text – conceived in the early post-war years when antimicrobials, the operating microscope and the National Health Service were all in their infancy – in an entirely new format that befitted modern surgical scholarship. Authors, editors and readers alike had become acutely conscious of the need to quote high-quality evidence to guide clinical decisions; the concept of grading clinical recommendations – and, by implication, acknowledging gaps in the evidence base of our practice – was born. Recognizing the enormity of Michael's contribution led us into the trap that has befallen every editor who has come before us; we grossly underestimated the task ahead. We had misjudged the pace of change. What began as an 'update' of some outdated chapters became a complete rewrite to reflect the advances that marked the decade between editions, but we were determined to keep the text to a manageable size. In the end, we have 330 chapters, but with a slightly smaller page count than the seventh edition.

The basic science knowledge that underpins our clinical practice is no longer focused just on anatomy and physiology; genetics, molecular biology, new techniques for auditory implantation, information technology, new medical therapies for many old disorders together with seismic changes in endoscopic technology and in medical imaging have transformed our specialty. Today's head and neck surgery would have been unrecognizable to the early authors and editors. Surgical oncologists have recourse to completely different treatment strategies than did their predecessors and now work as part of multidisciplinary teams. They deal with different disease patterns and vastly changed patient expectations. Thyroid and parathyroid surgery has become almost exclusively the domain of the otolaryngologist. Surgery of the pituitary fossa has come within our ambit, as has plastic and reconstructive surgery of the head and neck as well as aesthetic facial surgery. Neurotology, audio-vestibular medicine, rhinology and paediatric otolaryngology are accepted subspecialties, each with its own corpus of knowledge and skills and each warranting a sizeable section of this text. Contemporary otolaryngology is now a collection of subspecialty interests linked by common 'stem' training and a shared passion for looking after patients with disorders of the upper respiratory tract and the head and neck.

There is a view that a single text – even a multivolume tome of this size – cannot cover the entire knowledge base of modern clinical practice. The subspecialist will, of course, need recourse to supplementary reading. The pace of change shows no sign of slowing down, but there is still a need for a comprehensive working text embracing the whole spectrum of our workload. That was the task we set our authors and section editors; we think they have done our specialty proud.

In the new 'digital' editorial world authors create manuscripts on personal computers. They transmit chapters, figures, amendments and revisions across continents and time zones with a few keystrokes. The bulky packages containing grainy photographic prints and the reams of paper with closely-typed and heavily scored text that accumulated on authors' and editors' desks are a distant memory. References, guidelines and systematic reviews are all available online; the editorial 'red pen' has been replaced by a cursor on the screen. This 'new age' has enabled us to look ever further for expertise. We are proud to have enlisted the support of authors from more than 20 countries for this edition. *Scott-Brown* always enjoyed particular affection and respect in Asia, Australia, Africa and the Middle East. It has been a joy to welcome authors in increasing numbers from many of these parts of the world. We are now a truly global specialty and the eighth edition fully reflects this.

What has not changed is the huge time commitment authors and editors need to make. That time now has to be fitted into an increasingly pressurized work environment. Revalidation, mandatory training, more intense regulatory scrutiny, expanding administrative burdens and ever-expanding clinical commitments leave little time for scholarship. Our section editors are all busy clinicians. They have generously given their time, first instructing authors, cajoling them and then editing their chapters, virtually all of which have been completely rewritten since the last edition. Each author was chosen because of his or her specific clinical and scientific expertise and none has disappointed. Authors and section editors receive no reward other than the satisfaction of knowing that they have made a contribution to teaching and learning in a specialty that has given us all so much professional satisfaction. We are profoundly grateful to them and hope that their endeavours spur the next generation of otolaryngologists to carry on this noble tradition. *Scott-Brown* simply wouldn't happen without this generous and dedicated commitment, unstintingly and graciously given.

It is impossible to produce a book like *Scott-Brown* without the contribution of many individuals working behind the scenes. We would like to express our gratitude to our Publishers, Taylor and Francis, and to the staff who have worked on this project from its early days in 2011 to publication in 2018. In particular we would like to mention Cheryl Brandt who with good humour and patience helped to reel in many of the 330 chapters. Miranda Bromage joined the team in 2016 and her publishing experience and enthusiasm for medical education have helped guide this new edition through its final phases to publication. Finally, we are indebted to Nora Naughton who has dedicated so much more than just her extensive publishing skills to this project. Nora's meticulous attention to detail, combined with her warmth and wisdom have encouraged us all at the end of this endeavour.

We are truly 'passing on the torch' of a huge amount of accumulated knowledge and wisdom; it is this that gives us, the Editors-in-Chief, the greatest pleasure.

Read on and enjoy, our thoughts are yours.

RWC
JCW

I wish to acknowledge the love, happiness and inspiration that have been passed on to me by both my parents and grandparents. I recognise and value the friendship of my dear friend Ray Clarke who has been with me all the way on this rewarding and worthwhile endeavour. I would specifically like to thank Esme, Helen and William, without whom none of this would have been achievable. Their love and support has helped guide me through the years leading up to the publication of this tome, and my final thanks go to Angela Roberts and Sally Holden for their typing and editing skills.

JCW 2018

Thanks to my wife Mary for her patience and support. My parents, Emmet and Doreen Clarke, both sadly died during the preparation of this book. They would have been proud to have played a part in such a scholarly enterprise.

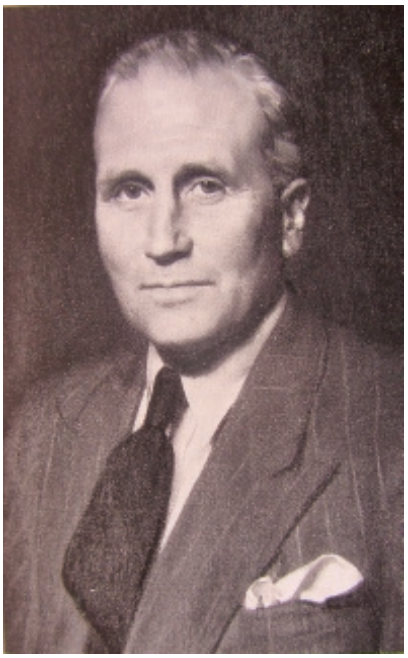
A Tribute to Bill Scott-Brown



Walter Graham ('Bill') Scott Brown. 1897–1987

Walter Graham ('Bill') Scott-Brown was twenty-three when he arrived at Corpus Christi College Cambridge in 1919. One of the generation of young men whose entry to university and the professions was delayed by their participation in the First World War, he had joined the Gunners in 1915 as an 18-year-old. He considered himself blessed to have survived – although wounded – when so many of his contemporaries never returned from the Front. In those early post-WW1 years the medical school at St Bartholomew's ('Barts') in London was keen to attract 'gentlemen'. To this end a series of scholarships – 'Shuter's scholarships' – was established to lure those with humanities degrees from Oxford and Cambridge into medicine. It was via this scheme that the young Scott-Brown qualified MB, BCh in 1925. By now married to Margaret Bannerman, one of the very few women medical graduates of her generation, the two established a general practice in Sevenoaks, Kent. His work here involved looking after children with poliomyelitis, which was then commonplace, and his MD thesis was on polio-related bulbar palsy. It earned him the Copeman Medal for research from the University of Cambridge. While working in general practice, Bill pursued his interest in the then fledgling specialty of otolaryngology, securing fellowships from London and Edinburgh. Postgraduate training was haphazard; there were no structured programmes or even junior posts, so the young Scott-Brown was fortunate to be awarded a Dorothy Temple Cross Travelling Fellowship. Mrs Florence Temple Cross had set up these awards (now administered by the Medical Research Council) in memory of her daughter, who died in 1927 aged thirty-two. They were made available to young physicians to help them travel to overseas centres specifically to study tuberculosis, then rampant and one of the commonest causes of death in young adults. The young Scott-Brown visited the leading pioneers of the day in Berlin, Vienna, Budapest, Stockholm, Copenhagen, Madrid and Venice. Here he developed his considerable endoscopy skills. He reported that his first bronchoscopies were done on a Venetian street entertainer who, for a few coins, would inhale sundry objects that the doctors would then dexterously retrieve from his main stem and segmental bronchi – without of course any anaesthesia!

Times were lean on Scott-Brown's return. Margaret ('Peggy') was now a popular and well-established GP who supported him as his private practice developed. Eventually he secured appointments at East Grinstead, the Royal National and Royal Free Hospitals. He had a thriving Harley Street practice and was the favoured otolaryngologist of the aristocracy. His reputation was such that he become laryngologist to the Royal family, was appointed Commander of the Victorian Order and was a particular favourite of the then Princess Royal, HRH Mary the Countess of Harewood.

By 1938 he was wealthy enough to purchase a farm in Buckinghamshire where he bred prize-winning shorthorn cattle. Ironmongery and blacksmith work were hard to come by during the war years, so Scott-Brown prided himself on his ability to make his own agricultural implements, cartwheels and farm wagons in a makeshift forge he himself established on the farm. He would while away endless hours here at weekends following a busy week in London. An accomplished fly fisherman, he was part of the exclusive Houghton Club whose members fished the River Test in Hampshire, where he numbered aristocrats including the Prince of Wales among his circle.

Scott-Brown's celebrated textbook came about in the early 1950s, when he became ill with jaundice and heart trouble. He was advised to rest, and took 6 months off work. Not satisfied with editing what has become the standard UK textbook, he took up painting as well. He became a celebrated artist whose work is still prized in many private collections. One of his pastels is reproduced on the preceding page.

Bill Scott-Brown lived to be 90. He died in July 1987, six weeks after his beloved Peggy and just as the fifth edition of the celebrated textbook that still bears his name was going to press. His legacy lives on in the pages of this book, and we are proud to continue the tradition of scholarship and learning which he established all those years ago.

We would like to thank Martin Scott-Brown for his help in compiling the biography above.

John C. Watkinson and Raymond W. Clarke
London, 2018

Acknowledgements

We acknowledge our debt of gratitude to the many authors who have contributed to previous editions of Scott-Brown's Otorhinolaryngology, and in particular to authors from the seventh edition, published in 2008. We are also grateful to Neil Bateman who helped with the initial planning of the Paediatrics section.

Chapter 10, **Management of the hearing impaired child,** contains some material from 'Investigation management of deaf child' by Sujata De, Sue Archbold and Ray Clarke. The material has been revised and updated by the current author.

Chapter 28, **Stridor,** contains some material from 'Acute laryngeal infections' by Susanna Leighton. The material has been revised and updated by the current author.

Chapter 31, **Acquired laryngotracheal stenosis,** contains some material from 'Jugular foramen lesions and their management' by Kees Graamans. The material has been revised and updated by the current author.

Chapter 97, **Imaging of the temporal bone,** contains some material from 'Anatomy of the skull base and infratemporal fossa' by Charlie Huins. The material has been revised and updated by the current author.

Chapter 106, **Non-vestibular schwannoma tumours of the cerebellopontine angle,** contains some material from 'Evaluation of the skull base patient' by Ranit De and Richard M Irving. The material has been revised and updated by the current author.

CHAPTER 1

INTRODUCTION TO PAEDIATRIC OTORHINOLARYNGOLOGY

Raymond W. Clarke

SEARCH STRATEGY

The author's personal bibliography formed the basis for this chapter. Some material is reproduced from '*Clarke's Paediatric otolaryngology – practical clinical management*'.[1]

HISTORY OF PAEDIATRIC OTORHINOLARYNGOLOGY

Laryngology

Otorhinolaryngologists have been caring for children since the specialty began. Diphtheria, epiglottitis and laryngeal tuberculosis were commonplace in children throughout the 19th and early 20th centuries. Victorian and Edwardian laryngologists such as Morell Mackenzie and Sir Felix Semon in London had large paediatric practices and dealt with these often-fatal upper respiratory tract pathologies. Semon was laryngologist to the British Royal family and undertook tonsillectomy on the grandchildren of Queen Victoria, making tonsillectomy a fashionable intervention in the drawing rooms of the aristocracy.[2–4]

Gustav Killian pioneered suspension laryngoscopy in Freiburgim Breisgau at the beginning of the 20th century and the technique was soon taken up for children. Chevalier Jackson (**Figure 1.1**) in Philadelphia established a reputation throughout the United States and beyond for his skills at tracheobronchoscopy. A brilliant teacher, he illustrated his work in his own hand and was probably the single most important figure to popularize airway endoscopy in children on both sides of the Atlantic.[5–7]

Sophisticated diagnostic and therapeutic procedures in children are only possible because of the huge advances made in improving the survival and care of small babies. Joseph O'Dwyer (New York) is credited with the first successful emergency endotracheal intubation in a child in 1884 (**Figure 1.2**), but the technique was associated with a high mortality. Long-term nasal endotracheal intubation as an alternative to tracheotomy was popularized only from the 1960s onwards; paediatric otolaryngologists are acutely aware of the debt they owe to paediatricians and anaesthesiologists. Wilson published the first English-language textbook of paediatric otorhinolaryngology (ORL) in 1955 (**Figure 1.3**) and wrote of emergency tracheotomy in children: 'these are desperate cases at best, and it may be a comfort to remember that the worst thing which can happen is that the patient will die. This is unfortunately a likely event in any case.'[8]

The pioneering work of British physicist Harold Hopkins in the design of 'rod-lens' telescopes (**Figure 1.4**)

Figure 1.4 Paediatric airway endoscopy using Hopkins rod lens.

moved paediatric airway surgery to new levels.[9] Modern-day airway endoscopy in children is a highly skilled – and safe – undertaking and the fear and trepidation that surrounded tracheostomy in children is a distant memory.

Otology and audiology

Mastoid surgery in children was popularized by Sir William Wilde (1815–1878). Wilde described otitis media with effusion – 'strumous otitis', recognizing its association with Eustachian tubal dysfunction.[10, 11] He advocated tympanocentesis as a treatment and pioneered the use of the myringotome (**Figure 1.5**). He was an early advocate for the recognition and education of the deaf child, but the profession of audiology really began in the 1920s when audiometers became available. Edith Whetnall in London established a network of clinics which became a model for the assessment and treatment of hearing-impaired children; her 1964 textbook *The Deaf Child* was the standard work for many years.[4]

Cochlear implantation, developed in the 1970s and refined and improved upon throughout the next 30 years, has transformed the lives of hearing-impaired children and their families in the developed world.

The assessment and rehabilitation of the hearing-impaired child has advanced greatly in recent years, and paediatric audiology is an important and growing medical specialty.

Societies and associations

Gatherings of otolaryngologists with an interest in ORL in children took place in Eastern Europe from the beginning of the 20th century. In the United States the Society for Ear, Nose and Throat Advances in Children (SENTAC) (https://sentac.org/) met in 1973. The American Society of Pediatric Otolaryngology (ASPO) (htpp://aspo.us/) was founded in 1985. The European Working Group in Pediatric ENT was founded in 1977 and later became the European Society of Pediatric Otorhinolaryngology (ESPO) (http://www.espo.eu.com/), a forum for discussion and advances in paediatric ORL through international

direct sunlight, I introduce this small, sickle-shaped knife,—with a double-cutting edge, and here figured of the natural size in the blade,

Figure 1.5 Wilde's myringotomy knife as illustrated by Wilde in *Practical observations on aural surgery: and the nature and treatment of diseases of the ear.*[10]

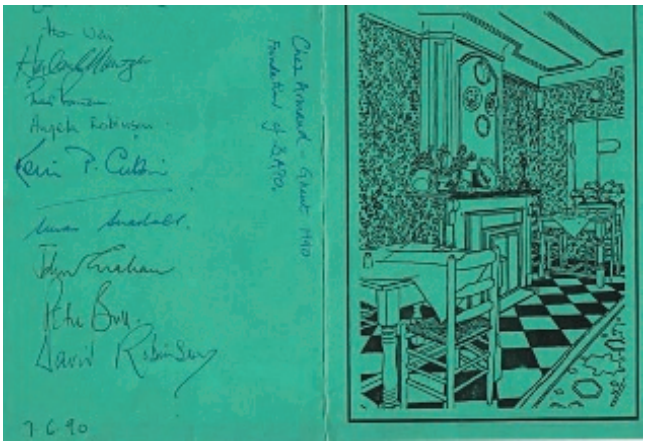

Figure 1.6 Menu from Ghent 1990, foundation of BAPO.

meetings and via its journal the *International Journal of Pediatric Otolaryngology*. The British Association for Paediatric Otolaryngology (BAPO) (https://www.bapo.co.uk/) was formed in 1991. The idea for a British society came about at a meeting of colleagues attending the international congress at Ghent in 1990. Surviving mementos include a signed menu from the Chez Armand restaurant (**Figure 1.6**) (John Graham FRCS, personal communication)!

DEVELOPING ENT SERVICES FOR CHILDREN

Advocating for children

ORL is the specialty with the biggest paediatric surgical workload. It is important that ORL clinicians are to the fore in driving service changes forward to best serve children, families and the next generation of specialists. Up to 30–50% of our workload involves the care of children. Otolaryngologists have, and must maintain, an important role as strong advocates for children.

The philosophy and thinking that influences how we care for children has undergone a radical transformation in recent years. Doctors are no longer seen as infallible. Parents are well informed and expect full participation in decision-making. They expect that their child will be treated in an environment that serves the needs of the child and family and that carers and other staff are fully trained not only in delivering health care, but also in the principles of looking after children and families. There is a growing expectation that service organization should be driven not by the needs of professionals but by the needs of children and families. These legitimate expectations put an onus on us as doctors and planners when setting up services for children. Despite the desirability of treating children close to home, children with unusual or complex conditions or who are in need of highly specialized intervention will have their care best delivered in one of a small number of more specialized settings, where resources and skills are concentrated.

Hospitals that undertake the care of children need to commit to exemplary standards, with the involvement of senior staff in ensuring that the specific requirements of children are met.[12] In a hospital with several otolaryngologists on staff, one should ideally be designated as lead for paediatrics so that he/she can advocate for children at the highest level and can coordinate management, transfer and referral of children with complex needs who may need treatment in a specialized centre. Well-established liaison networks and good communication with specialist centres, paediatricians, community paediatric services, social services, parents and advocacy groups are a cornerstone of good paediatric practice.

Organizing clinics and theatre

Children are best seen in a designated children's clinic rather than in a mixed adult and children's setting.

The clinic setting should be 'child-friendly' with suitable toys, papers and pens and facilities for parents and siblings (see Chapter 2, The paediatric consultation). Similarly, it is nowadays accepted best practice that surgical lists should be planned so as to permit 'children only' lists rather than mixed adult and child surgery.[12]

Theatre staff looking after children need to be suitably trained and in particular the anaesthesiologist should be competent in paediatric anaesthesia with a sufficient workload and throughput to maintain his/her skills in the peri-operative care of children. Children under the age of 3 years will usually require more specialized anaesthetic care. The professional associations that govern anaesthesia in different jurisdictions have their own recommendations with which anaesthesiologists will generally be familiar. If at all possible and provided it is safe, children should be admitted and discharged on the same day ('day' surgery or 'ambulatory care').

Children are best looked after in a children's ward rather than in a mixed ward with adults, again with appropriately trained and accredited nursing staff. Provision should be made for parents, who will usually wish to stay with the child overnight.

If children require overnight nursing care – for example, following adenotonsillectomy for obstructive sleep apnoea (OSA) – experienced paediatric ear, nose and throat (ENT) nurses are usually best placed to look after them. A small number of children will need more thorough monitoring and supervision, perhaps with one-to-one nursing care, or admission to a high dependency unit (HDU) or, exceptionally, to a paediatric intensive care unit (PICU).

TRAINING THE OTORHINOLARYNGOLOGISTS OF THE FUTURE

The diagnosis and management of ORL conditions in children forms an essential part of the syllabus for all ENT surgeons in training. Examinations in ORL – including the European Board Examination[13] – put much emphasis on this, and in general otolaryngologists are well trained in the principles of looking after children with common disorders of the upper respiratory tract.

Although subspecialization in ORL is largely 'system' (otology, head and neck surgery, rhinology) rather than age-based, a growing number of otolaryngologists now choose to undertake advanced training in a fellowship programme in one of the major children's hospitals with a view to taking a special clinical interest in the care of children. In addition to basic and fellowship training, all of us who care for children need to have up-to-date knowledge and skills in topics such as child protection, prescribing for children, analgesia and paediatric resuscitation, and continue to maintain and refresh our knowledge and skills.

BEST CLINICAL PRACTICE

- ✓ Clinicians caring for children and young people should undertake a level of paediatric clinical activity that is enough to maintain minimum competencies.
- ✓ Children should be treated safely, as close to home as possible, in an environment that is suited to their needs, with their parents' involvement in decisions, and with the optimal quality of care.
- ✓ Where theatre scheduling permits, children should have their surgery performed on a dedicated children's operating list.

FUTURE RESEARCH

- ➤ There is an increasing trend to centralize children's surgery. Otolaryngologists must ensure they are to the fore in local service planning.
- ➤ ENT surgeons need to take a strong advocacy role to make for better services for children.
- ➤ Training in the generic skills required to care for children is essential to ORL practice.
- ➤ Training in paediatric emergencies should be encouraged for all ORL practitioners who look after children.

KEY POINTS

- Paediatric otorhinolaryngology is as old as the specialty of otolaryngology itself.
- The pathophysiology and natural history of disease may be very different in children.
- Looking after children is an integral part of the work of an ORL specialist.
- Developments in medicine, anaesthesia and intensive care have brought about a need for increasingly specialist care for children with ORL disorders.
- The improvements in endoscopy brought about by the discoveries of Harold Hopkins transformed paediatric airway care.

CHAPTER 2

THE PAEDIATRIC CONSULTATION

Raymond W. Clarke

SEARCH STRATEGY

Data for this chapter are mainly drawn from the author's personal bibliography. The websites of the General Medical Council (GMC) (http://www.gmc-uk.org/), the Royal College of Surgeons of England (RCS) (https://www.rcseng.ac.uk/), the Department of Health (DoH) (https://www.gov.uk/government/organisations/department-of-health), General Medical Council: http://www.gmc-uk.org and the National Institute for Health and Care Excellence (NICE) (https://www.nice.org.uk/) were also consulted.

INTRODUCTION

Children and their parents will often vividly remember their encounters with a doctor. The child's first contact with medical staff and hospitals sets the scene for subsequent visits. A good paediatric consultation is more than a forum for making a diagnosis and planning management; it is an opportunity to familiarize the child and family with the hospital, the clinic, and the members of the team who will look after them during one or more admissions and outpatient visits. For the doctor, it is often the beginning of a rapport with a family who may need to see you many times over the ensuing years. Attention to a few details makes for a far better experience. It is worth putting time, effort and preparation into making the exchange as pleasant and productive as possible for the child and family.[1–4]

The principles that make for a satisfactory and worthwhile visit to the otorhinolaryngology (ORL) department apply to both adults and children, but some features of the children's clinic are unique. The decision to seek advice will have been made not by the patient but by the parent(s) or carer. The older child will express her views; with babies and young children you are essentially looking after a family rather than a patient. The history, the diagnosis, the discussion of management options, and the decision-making are 'by proxy' and will usually involve the parents – sometimes alone, and sometimes in consultation with the child.

BUILDINGS AND FACILITIES

The clinic experience for the family starts well before they see you. Easy road access, car parking, a bright friendly environment with adequate outlets for food and drinks, baby-feeding facilities, wheelchair-friendly access and an environment where children and parents feel safe and welcome contribute greatly to parental and child satisfaction with their visit. Planning modern children's hospitals and facilities is a highly skilled and complex endeavour. It requires close liaison between the architects and their design team, clinicians, hospital staff, children and their advocates, and planning authorities (**Figure 2.1**).

Despite their small size, children need proportionately more space than adults. Seating has to be comfortable and suitable for all ages. Wheelchair access is essential as are spaces for breastfeeding, well-equipped bathrooms and facilities for changing of babies' clothes. A bright spacious waiting room well stocked with toys, pens, paper, crayons and computer games and able to

Figure 2.1 Foyer of Royal Liverpool Children's Hospital.

Figure 2.2 Waiting room with toys.

withstand the rough and tumble that is inevitable in a group of children will make for a far happier experience than a cramped facility (Figure 2.2).[5] Children become bored and fractious if they wait too long or have not got enough space.

Play therapists are invaluable and, if the hospital authorities can be persuaded to hire a professional entertainer, better still.

An examining room should be able to accommodate not just the patient, doctor and nurse but two parents, one or more siblings, sometimes in 'Moses baskets' or pushchairs, and often a grandparent. In the case of many of the children with special needs who make up a sizeable proportion of referrals to an ORL service, there may be a need to accommodate a wheelchair, oxygen cylinders and the various bits and pieces the parents carry for tracheotomy care and gastrostomy management. Ideally, an examining room should have a small play area as well where the child and siblings can occupy themselves while the mother gives the history and the doctor can quietly observe the child. The physical environment must be safe for the child, with no spirit lamps, sharp instruments or corners. Discreetly put away instruments other than those in frequent use. Small children will be frightened at the sight of an array of picks and hooks. Handwashing facilities are mandatory. An operating microscope is nowadays essential, either in the room or nearby. Endoscopy – both flexible and rigid – is now so frequently performed in an outpatient setting in children that it can be regarded as a standard requirement in a paediatric ORL clinic. A range of scopes – with facilities for safe storage – and ideally a monitor and a high-specification image capture system with a printer are nowadays mandatory.

Audiological testing rooms should be adjacent to the clinic so that the child can easily move from one to the other.

STAFFING CHILDREN'S CLINICS

Paediatric clinics need more nursing support than general ENT clinics.[6] Reception staff and care assistants with the training and expertise needed to deal with parents and children make for a far better clinic experience. Best practice is that a registered children's nurse should be available 'to assist, supervise, support and chaperone children'[1, 2] but arrangements will vary in different jurisdictions and in different healthcare settings. Staff numbers need to be sufficient not only to support the working of the clinic, but also to ensure the safe supervision of patients and their siblings while parents are preoccupied.

Audiological professionals are an integral part of paediatric ENT practice; a fully registered audiology technician with facilities for audiometry and tympanometry should be available for all children's ENT clinics.

Other professionals may be needed depending on the nature of the clinic: a speech and language therapist (SALT) for voice disorders or cleft palate, or specialist audiological personnel for children with bone-anchored hearing aids (BAHAs) or cochlear implants (CIs).

Trained specialist nurses who liaise with families in the community – for example in supporting home tracheostomy care – greatly enhance the clinical experience for parent and child. Some units arrange a 'preadmission' clinic so that when a child is scheduled for surgery she can

have her pre-op checks in advance of the day of admission. A dedicated nurse usually runs these clinics, and it can be useful for the family to meet her/him at the first clinic visit so that they can plan ahead.

PREPARING FOR THE CONSULTATION

Ideally, the children's clinic must be separate from the adult clinic. If it is not possible to have a clinical area and a set of consulting rooms that are used exclusively for children throughout the working week, they should be scheduled for a dedicated paediatric session; children should no longer be seen in a 'mixed' adult and paediatric setting. It can be very uncomfortable for children and families if they are allocated the same clinic and have to share a waiting room with a group of adult patients.

Adolescents may feel uncomfortable surrounded by hordes of small children and need to have their particular needs catered for. Some hospitals have separate clinics for adolescents planned for after school times, and teenagers usually appreciate a separate ward or section of a ward if they need inpatient care.

There is much to be said for running separate clinics for some categories of patients. These may include 'special needs' clinics and clinics where multidisciplinary input is required, for example audiology, cleft palate and plastic surgery. Plan the optimum organization of time and space in such clinics to strike a balance between making the most efficient use of time by all concerned and the need to ensure you do not overtire or overwhelm the child by asking her to see too many adults in one room at one time.

A visit to the hospital is a routine event for the doctor. It is a major episode in the life of the child and parent.

Remember that the parent/carer is likely to have had to make arrangements in advance of their visit. They may have had to book time off work, childcare for siblings, a day off school for the child, and transport for the trip.

Take time to read the case-notes – often electronic nowadays – including the results of investigations if applicable, and learn the child's name before the consultation starts. If the child has a chronic medical condition or a syndrome, read up on it in advance if you can. This is relatively easy nowadays as so much information is available online. Parent and child will appreciate continuity and, if a child needs to be seen for repeat visits, it is ideal if the same doctor sees them each time.

Make sure parents or children do not feel rushed in clinic; if you have to hurry them along, the clinic has not been properly planned. If family members do not speak the same language as the doctor and clinic staff, an interpreter will be needed, and this should be arranged well in advance of the visit.

It is not the author's place to advise on dress code; suffice to say that your best tailored suit and crisp, freshly pressed shirt will neither impress the average 8-year-old nor continue to look crisp at the end of a busy morning with a succession of spirited children!

THE HISTORY

Welcome the family and greet the child by name. Make eye contact and start by introducing yourself. Introductions should include others in the room; ask permission for medical/nursing students to be present and for them to examine the child. Multidisciplinary clinics can be particularly intimidating as several specialists are present. It is good practice for all to wear a name badge and many hospitals will demand this. Establish who is with the child – it may be a parent, a carer or a grandparent. Be clear on who is going to give you the history and make sure the child gets an opportunity to speak if she is old enough. Doctors are taught to take very focused histories, but in a paediatric setting it is often better to ask an open question, such as 'What are your worries about Kirsten?', than to steer the parent down a particular set of symptoms.

Good consultation skills can be taught, learnt and improved upon with constructive feedback and should be an important part of training and assessing surgeons as they progress towards independent practice.

Many doctors regard themselves as good communicators because they can explain illnesses and procedures in easy-to-follow terms, but of course communication is a two-way street. Listening – without interruption – can be more useful than talking. It is essential that the parent – usually the mother – feels that her account has been carefully listened to and understood before you probe with more direct questions. Watch the child, look at the mother's facial expressions, note how she interacts with the child and pick up as much information as you can from both verbal and non-verbal clues.

Listen well and talk less until it is clear that the parent feels you have the full picture.

If the parents offer to show you the child's growth chart, a record of their visits to the doctor, diary entries, photographs or short video clips, make sure you look at them. The parents will feel any record of their child's health is important and they may give you much information, for example about the child's overall development or, in the case of video clips, the child's sleep pattern. The birth and perinatal history may be important, and particularly with airway pathology it is helpful to ask the mother about the delivery, whether the baby was term or premature, whether there were any concerns about breathing and feeding as a newborn and in particular

whether there was any airway intervention such as an endotracheal tube or a period in the special care baby unit (SCBU).

EXAMINATION

Begin the examination as soon as the child comes into the room. Note the child's gait, breathing pattern and state of alertness. Once they have had a chance to settle in the clinic room, young children are usually happy to be examined. Smaller children are best examined sitting on their mother's knee.

For the ENT examination explain in an age-appropriate way what is going to happen; don't persist if the child is fractious or struggling.

It is not appropriate to restrain an older child for the purpose of an elective clinical examination, but the mother/father can gently but firmly hold a baby or toddler to facilitate otoscopy, examination of the nose and examination of the neck (Figure 2.3).

Most children will tolerate otoscopy; if there is wax or debris, it is usually possible to remove it by suction to get a better view. Use the biggest speculum that will comfortably fit in the ear canal. If you need a better view, use the microscope, which should be as well tolerated as a standard otoscope. Thin otoendoscopes with high-quality cameras and viewing monitors are becoming more widely available and represent a good opportunity to record findings, to facilitate better explanations of pathology to parents and to use as an aid to teaching.

A good way to start a nasal examination is to assess the nasal airway using a cold metal spatula to look for the pattern of condensation (Figure 2.4). Children do not like the Thudicum's speculum; you can get a good view of the nasal cavities by elevating the tip of the nose and looking with a good light source (Figure 2.5) but high-quality modern endoscopes have made rhinoscopy far easier and better tolerated. Although some surgeons like to use a local anaesthetic spray, the author has not found this useful and in general, if a child will not tolerate a nasendoscope, she will tolerate a spray even less; get the best view you can using a headlight.

Figure 2.3 Examining a child.

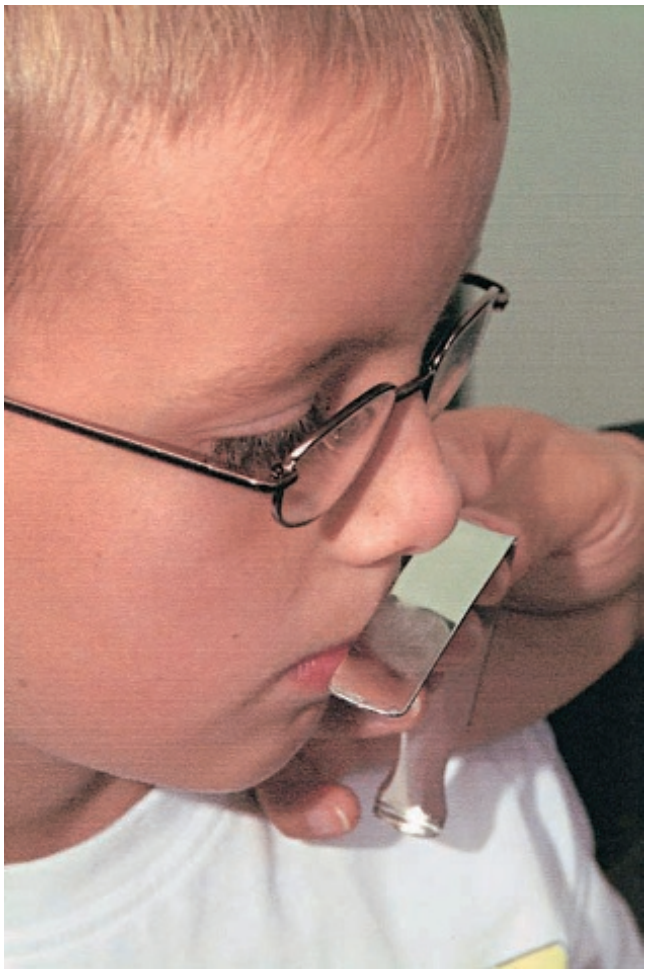

Figure 2.4 The spatula test.

Figure 2.5 Nasal examination.

Examine the pharynx with a standard headlight. Children dislike tongue depressors; the author very rarely uses one. You can get a good view of the nasopharynx using a telescope with an angled lens carefully placed between the tonsils.

Examining the larynx can be difficult, but flexible transnasal endoscopy will give you a very good view in a

cooperative older child, or in the case of a baby who is gently but firmly held by the mother. As with nasendoscopy, the author has not found local anaesthesia very helpful. You may be able to see the vocal cords with an angled-lens rigid telescope but, if a child is anxious or distressed and you have to get a view of the larynx, then arrange admission for a general anaesthetic.

Neck examination should focus on observation for lumps, bumps, sinuses and asymmetry, gently palpating to assess for lymph nodes. 'Lymphadenopathy' is probably a misnomer in children as some degree of lymph node enlargement is physiological and should cause no alarm.

INVESTIGATIONS

Few if any investigations are needed for most common ENT presentations in children.

Pure-tone audiometry (provided the child is old enough) and tympanometry are essential components of a full ENT examination. Radiological imaging may be needed depending on the pathology, and ultrasonography is increasingly used to quickly assess neck swellings. Some ENT surgeons are now skilled at getting good ultrasound images in clinic. If the child needs blood tests, then she should have local anaesthetic cream (e.g. EMLA™ cream, an emulsion containing lidocaine and prilocaine) before being sent for phlebotomy. Photography can be useful – for example, for facial and neck lesions – and close liaison with a skilled medical photography department will make for a better paediatric ENT service.

MANAGEMENT PLAN

The parents have come to see you to hear your opinion on their child's condition and to discuss a management plan with you. This part of the consultation is vital and must never be rushed. Explanations should be straightforward and easy to understand, involving the child where appropriate. Models, diagrams, printed and audiovisual material can aid this process greatly. For many interventions, such as tonsillectomy, adenoidectomy and insertion of tympanostomy tubes, there will be more than one management option and it is important that each is discussed in an open and honest way. This sometimes means doctors have to admit doubts and uncertainties and these are best explained without embarrassment so that a way forward can be agreed by consensus. The treatment will be a matter for negotiation between the otolaryngologist and the mother and/or child and questions should be encouraged. Some parents see the ORL consultation as a means to confirm a treatment option they have already decided on with their family doctor (e.g. tonsillectomy for recurrent sore throats). Others are reluctant to consider any surgery, but all will greatly appreciate an informed discussion and an honest presentation of the evidence for current practice focused on the specific needs of their child. In general, parents appreciate a discussion with the senior clinician, but this needs to be balanced with the need for residents and juniors to see patients and improve their diagnostic and consultation skills.

PAEDIATRIC MEDICAL ASSESSMENT

ENT surgeons are not typically trained medical paediatricians; if you are seeing a significant number of children, you will come across conditions that are best diagnosed and dealt with by paediatrician colleagues. Some knowledge of these conditions can help early detection and referral so that parents and children are offered skilled support as soon as is practicable. Attention deficit hyperactivity disorders (ADHD), autistic spectrum disorders (ASD), and a variety of 'functional' disorders may well present first to the otolaryngologist.

ADHD

Every clinician will be familiar with the child who fidgets, won't sit still, and seems to have a poor attention span. Parents will often volunteer that the child is 'hyperactive' or disruptive. In extreme cases this may constitute a behavioural syndrome termed attention deficit hyperactivity disorder (ADHD). This condition is now thought to affect 3–4% of children worldwide. They occasionally present with suspected hearing loss or poor sleep patterns.

The defining features of ADHD are hyperactivity, impulsivity and inattention, but these characteristics are distributed in varying degrees throughout the population.

ADHD diagnostic criteria vary somewhat, but the core feature of the diagnosis is that symptoms are associated with 'at least a moderate degree of psychological, social and/or educational or occupational impairment'. ADHD is not a categorical diagnosis; it should only be made with great care following a thorough assessment by a skilled and experienced paediatric team.[7] A diagnosis of ADHD has serious potential implications; it is generally a persisting disorder. Most affected children will go on to have significant difficulties in adulthood, including continuing ADHD, personality disorders, emotional and social difficulties, substance misuse, unemployment and involvement in crime. Management can be very taxing, involving social and educational services, the family doctor and his/her team, specialist paediatricians and, of course, the child's family.

Autistic spectrum disorders

Autism was once thought to be an uncommon developmental disorder but is now estimated to occur in at least 1% of children. Healthcare personnel need to be aware of some of the features so as to facilitate early diagnosis and intervention. The characteristic features are impairment in reciprocal social interaction and social communication,

TABLE 2.1 Some features of autistic spectrum disorders (ASD) in preschool children

Aspect	Examples
Language	Delayed speech development Frequent repetition of set words and phrases
Responding	Not responding to their name being called Rejecting cuddles
Interacting	Unaware of other people's personal space Intolerant of people entering their personal space Avoiding eye contact
Behaviour	Repetitive movements Playing with toys in a repetitive way Getting upset if there are changes to normal routine

combined with restricted interests and rigid and repetitive behaviours. In recognition of the great heterogeneity of autism, the term 'autistic spectrum disorder' (ASD) is now more commonly used. The list of possible symptoms is very large but some key features are shown in Table 2.1.

Otolaryngologists may suspect that a child referred for a hearing or speech assessment has an ASD. The diagnosis needs to be made with great care and warrants a full assessment by an experienced team.[8] If ASD is confirmed, families and the child or young person themselves can experience a variety of emotions, including shock and worry about the implications for the future. Some have a profound sense of relief that others agree with their concerns. Skilled diagnosis is important: it can offer an understanding of why a child or young person is different from their peers, open doors to support and services in education, health and social care, and provide a route into voluntary organizations and contact with other children and families with similar experiences. All of these can improve the lives of the child or young person and their family.

Children with ASD may present to the ENT clinic with language delay or suspected hearing loss.

Given the frequency of the condition, many children who present to the ENT clinic will have a background history of ASD and it is important to be aware of the diagnosis because of its very common association with comorbidity. ASD is strongly associated with a number of coexisting conditions. Approximately 70% of people with autism also meet diagnostic criteria for at least one other (often unrecognized) psychiatric disorder that further impairs their psychosocial functioning. Intellectual disability (intelligence quotient [IQ] below 70) occurs in approximately 50% of young people with autism. Deafness and other sensory impairments are more common and may be difficult to recognize.

Children with ASD need particularly sensitive care and attention if they are admitted for surgery.

Some children with ASD find the company of other children distressing and they are especially likely to become upset if they have to wait too long. In general they should be assessed early by the anaesthesiologist, considered for a sedative – 'pre-med' – scheduled early on the operating list, and discharged as soon as they are fit. Day surgery is preferable unless there are very good medical reasons to keep the child in overnight.

Functional disorders

Just as in adult medicine, children present to the ENT clinic with symptoms for which no organic pathophysiological explanation can be found despite a thorough examination and in some cases extensive investigation. The term 'functional disorders' is often used to emphasize that, although no structural or anatomical abnormality can be demonstrated for example on imaging, endoscopy or microscopy, there may be physiological dysfunction.

ENT symptoms in children may include:

- earache
- tinnitus
- hearing loss
- dysphagia
- neck pain
- balance disorders
- dysphonia
- stridor (very occasionally).

Terms such as 'medically unexplained', 'psychogenic', 'stress-related', 'psychosomatic' and 'hysterical' were used in the past but have been abandoned as they were unhelpful, became derogatory and implied a certain amount of 'blame' on the part of the patient.

Functional disorders are not the same as factitious or feigned illness; it is hugely counterproductive to make the child or parent feel that they are not believed.

The symptoms are very real to the patient and can cause great distress, which can be exacerbated if they are treated in an insensitive or judgmental way.

Take a full history, examine the child thoroughly, arrange investigations as needed – including audiometry, imaging and endoscopy – and formulate a diagnosis. If you suspect a functional basis for the symptoms, enquire into issues such as school, relationships with siblings, friends and family and whether there has been any change in home circumstances. Parental disharmony, bullying at school and the trauma of the physiological and psychological changes of puberty and adolescence can all have an impact on health and well-being, with somatic symptoms coming to the fore. An experienced clinician will need to strike a balance between a thorough investigation to rule out an organic aetiology and a more minimal approach focusing on history, examination and reassurance. A sensitive and thoughtful explanation of the findings to parent and child will allay fears and make for a good rapport for follow-up visits.

There is often a background history of environmental or psychological stress, but dealing with a certain amount of anxiety, uncertainty and insecurity is all part of

growing up. Children can – consciously or unconsciously – describe symptoms that bring about some 'secondary gain' for them, such as time off school, increased parental attention in the event of a new sibling, and the benefits associated with being perceived as 'sick'. Functional disorders are distinct from true malingering or feigned symptoms, although these do very occasionally present as well. It is difficult to know on the basis of a single consultation whether there is any significant psychological morbidity; too-early referral to a psychological support service can be counterproductive.

Many functional disorders are short-lived and should not be 'over-medicalized.'

It is the author's practice in most circumstances to reassure the family that the majority of these symptoms are transient and rarely need intensive intervention. Bear in mind that depression, pathological anxiety and rarely overt psychosis do occur in children, and skilled psychiatric help will be needed in some circumstances. Referral protocols vary but most children's hospitals will have a child and adolescent mental health service (CAMHS) team, who will see and assess children at short notice. Many hospitals will have specific policies covering this type of scenario; clinicians should ensure they have the appropriate training for the setting in which they work. Management must be tailored to the individual child and family and prognosis varies greatly.

CONSENT AND PARENTAL RESPONSIBILITY

It goes without saying that every medical intervention requires the informed consent of the patient. What is different in the case of young children is that they may not have the capacity and understanding ('competence') to weigh the benefits and risks of an intervention, and consent will usually need to be given on their behalf. It is wise to involve the child whenever possible. The interests of the child must, of course, take precedence over the wishes of others, even parents, and the law in almost all jurisdictions recognizes this, but clinicians will want to respect the legitimate concerns of parents, carers or legal guardians. The legalities that govern these processes vary in different jurisdictions and healthcare settings but the principles are broadly similar.

Once children reach the age of 16 years they are deemed legally 'competent' in the UK.

Reaching the age of legal competence means children are responsible for decisions relating to consent themselves, but it is of course wise to involve parents if at all possible in major decisions in the young. If a young person up to the age of 18 years is not 'competent' – for example, due to learning disability, reduced consciousness, or severe illness – then a parent or person with 'parental responsibility' (see below) can give consent for them, but over the age of 18 years in UK law a parent cannot give consent on behalf of a young person. This causes difficulties in the case of young adults with learning disabilities, many of whom remain under the care of children's hospitals. In these cases the clinician must make the decision on the young person's behalf, ideally with the written agreement of another senior clinician and with the full approval of the parent.

A child under the age of 16 years may well be able to understand the implications of a treatment strategy. In UK law such a child who has 'sufficient understanding and intelligence' to enable him or her to understand fully what is proposed is deemed 'Gillick competent' or as it is sometimes known 'Fraser competent'.[9] The decision as to whether a child fulfils the criteria for 'Gillick competence' rests with the clinician, hence teenagers undergoing, for example, tonsillectomy may give their own consent. The issues around consent in children can cause great sensitivity and are fraught with medicolegal pitfalls. If in any doubt, seek the advice of one or more senior clinicians.

In the case of a child who is not 'competent', consent has to be sought from and given by a person with 'parental responsibility.'

'Parental responsibility' is usually held by one or both of the parents. The situation varies in different jurisdictions but in England and Wales 'parental responsibility' is automatically given to the mother, and to most fathers. A father will have parental responsibility if he is married to the child's mother or listed on the child's birth certificate (after a certain date, which varies in jurisdictions). Fathers who do not have parental responsibility can get it via an agreement with the mother or they can apply for it through the courts. Grandparents, foster parents and others who look after children do not have parental responsibility unless special legal arrangements have been made. Consent from one parent is legally valid but it is best to obtain consent where applicable from both. A written record of consent, signed by the doctor and the parent, is an important document and, although not legally mandatory, in general an invasive intervention should not proceed without it. Verbal consent for surgery is possible – and in many circumstances entirely reasonable. If, for example, a newborn baby needs urgent surgery, very often the mother will be recovering in the maternity unit. The surgeon should speak to her by telephone, explain the natural history of the condition, the implications of treatment, the consequences of not treating, and the timing of treatment. It is good practice to get another healthcare professional (e.g. a nurse) to confirm with the mother that she understands and agrees with what is being proposed and to record the exchanges in the case notes.

It may be necessary in emergency scenarios to proceed without consent – for example when a child needs urgent

intervention following an accident and the person with parental responsibility is not immediately available.[10–13]

A recent UK legal judgement – the 'Montgomery' case – has moved the focus of consent more towards the specific needs of the individual patient. This follows the guidance of the General Medical Council[11, 12] but makes even more explicit the need for doctors to take reasonable steps to ensure that **patients are aware of any risks that are material to them.** This puts a greater onus on us as surgeons not only to communicate the benefits and risks of interventions but to judge the individual needs and perceptions of our patients/parents and to customize our discussion of management options to those varying patient/parent views.[14, 15]

Consent in children causes great sensitivity. Make sure you are familiar with the Department of Health guidelines,[10] the findings of the 'Montgomery' case,[14] the advice of the General Medical Council[11–13] and the guidance of the surgical Royal colleges.[15] Trainee surgeons in particular are advised to seek the advice of senior colleagues in the event of any uncertainties.

FUTURE RESEARCH

- Department of Health (DoH): https://www.gov.uk/government/organisations/department-of-health
- General Medical Council (GMC): http://www.gmc-uk.org/
- National Institute for Health and Care Excellence NICE): https://www.nice.org.uk/

CHAPTER 3

RECOGNITION AND MANAGEMENT OF THE SICK CHILD

Julian Gaskin, Raymond W. Clarke and Claire Westrope

SEARCH STRATEGY

Data in this chapter are taken from the Advanced Paediatric Life Support (APLS) manual and the websites and publications of the General Medical Council, the National Institute for Health and Care Excellence (NICE), and the Paediatric Intensive Care Society (PICS), supplemented by the authors' personal bibliographies and their experiences as clinicians and teachers.

INTRODUCTION

Children under the care of otolaryngologists are mostly looked after in an outpatient or planned inpatient setting, and are in good general health. Very ill children – sometimes with complex and multisystem diseases – are typically cared for by paediatricians and their teams, but the otolaryngologist will often participate in shared care. Every doctor who looks after children will, from time to time, be presented with an emergency situation; children who are apparently well can deteriorate very quickly.

Doctors who deal with children also need to be aware that children are vulnerable to harm and abuse and that we have a duty of care to recognize and act if we have any concerns about such abuse or maltreatment.

This chapter outlines some of the general principles that underpin the care of the very sick child, and highlights some of the features of child abuse that may present in an ORL clinic.

A short book chapter is, of course, no substitute for structured learning and experience. ORL training programmes now recognize this and both otolaryngologists-in-training and established practitioners will need to complete formal 'hands-on' training courses in the principles of resuscitation and in 'child protection'.

THE 'NORMAL' CHILD

The aphorism that 'children are not small adults' conveys important lessons, not least that the physiology of the child and their responses to illness may be very different from those in adults. Children have lower physiological reserves; they can deteriorate with alarming rapidity. Doctors who work largely with adults may not always appreciate, for example, the widely varying baseline observations in children, and their changes with age (**Table 3.1**). Fluid requirements are, of course, also very different in children (**Table 3.2**).

An awareness of the normal parameters is essential, as deviations away from these allow the clinician to recognize them at the earliest opportunity. Ongoing assessment and monitoring can facilitate early detection of change and prompt life-saving intervention.

RECOGNIZING THE SICK CHILD

The way we approach recognizing and managing seriously ill patients nowadays has largely been shaped by the principles developed in Basic and Advanced Life Support courses (BLS and ALS).[1, 2] Courses and teaching modules

TABLE 3.1 Normal range at different ages for children's weight, respiratory rate, pulse rate and systolic blood pressure (adapted from APLS manual[1])

Age	Weight (kg)	Respiratory rate (RR) (breaths/minute)	Pulse/minute	Systolic blood pressure (mmHg)
Birth	3.5	25–50	120–170	65–105
1 year	9.0	20–40	110–160	70–95
4 years	16.0	20–30	80–135	70–110
10 years	32.0	15–25	70–120	80–120

TABLE 3.2 Fluid requirements in normal healthy children (adapted from APLS manual[1])

Body weight	Fluid per day (mL/kg)
First 10 kg	100
Second 10 kg	50
Each subsequent kg	20

focused on the needs of healthcare personnel looking after sick children developed from the early 1990s as the Advanced Paediatric Life Support (APLS) system, which teaches a structured and reproducible set of skills applicable across specialty, language, cultural and geographical boundaries.[1] APLS teaching materials are produced and regularly updated by a multidisciplinary team of paediatric emergency physicians, anaesthetists, surgeons and paediatricians. Much emphasis is given to the care within the first hour, the so-called 'golden hour', which governs the trajectory of subsequent management. With important, easy-to-remember initial steps, the right order of resuscitation can begin to help avert a sick child deteriorating, or even worse, dying.

Prioritizing bodily systems has helped clinicians and those first on the scene to deal with complex situations in the best possible way. A structured approach concentrates on different systems of the body in an order that generally allows the most important problems to be assessed and dealt with first before moving on. These systems include the **respiratory**, **circulatory** and **central neurological** systems. They can be remembered as:

A – Airway
B – Breathing
C – Circulation
D – Disability (central neurological system)
E – Exposure (temperature, rash, bruising).

The respiratory system – airway and breathing

In the initial assessment of a sick child, the airway and breathing must be considered first. A blocked or reduced airway has to be addressed as a matter of extreme urgency as this impacts quickly on all of the organ systems. Signs to be observed include **apnoea**, **stertor** and **stridor**. As the child's ribcage is soft and pliable, sternal and intercostal **recession** and **'tracheal tug'** (indrawing of the suprasternal tissues) can often be seen if a child is working hard to breathe.

The respiratory rate must be measured. This will vary according to the child's age (see Table 3.1). If a child is tachypnoeic, this may be due to airway or lung pathology, or a metabolic acidosis (trying to 'blow off' carbon dioxide). A slowing respiratory rate is not always a comfort; it may be due to fatigue or cerebral depression and can be a preterminal sign.

Respiratory noises can help to define the level of airway narrowing, but this is not specific enough to make a definite diagnosis. If the noise is a low-pitched, snoring-type sound ('stertor'), then obstruction is usually at the level of the nasopharynx or oropharynx. 'Stridor' – generally a higher-pitched noise, (although the two terms are used imprecisely) – is often inspiratory but can also be biphasic (inspiratory and expiratory), and is classically brought about by obstruction in the larynx. This can be the supraglottis, glottis or subglottis but stridor can also be due to narrowing of the trachea or even the main bronchi. Biphasic stridor is particularly ominous and suggests severe airway compromise. Obstruction in the lower airway or in the distal bronchial tree will usually produce **wheeze**, which is more pronounced on expiration. All these respiratory noises are normally more pronounced in the presence of good airflow. In a preterminal state when the airflow is reduced, there may not be an obvious respiratory noise, despite significant obstruction within the airway. Beware the stridulous child who becomes quiet. Gasping is almost invariably a late sign of a severely hypoxic, exhausted child.

A child with severe airway obstruction will often adopt a position – usually when lying down – with the neck extended. This is called an 'opisthotonic' position and is aimed at trying to open the upper airway maximally due to obstruction. Other signs to look for in the assessment of airway compromise include flaring of the nostrils as an infant tries to increase the intake of air during inspiration.

Inspection, palpation and auscultation of the chest can reveal important signs too. Chest expansion can be a very sensitive sign when making an assessment of the amount of air passed during inspiration and expiration. The same goes for auscultation, where reduced air entry can be evaluated. If air entry is unequal across the lungs, this may point to pathology affecting one lung, such as a pneumothorax or a bronchial foreign body. A 'silent chest' is another late sign in a child that may be about to have a cardiopulmonary arrest.

Simple measurement of the pulse can inform the clinician of the presence of tachycardia associated with hypoxia. However, this is also likely if the child is anxious or pyrexial. Bradycardia is an ominous preterminal sign.

Monitoring equipment such as a pulse oximeter may be of additional support as it can help give a measure of the arterial oxygen saturation. Pulse oximetry should be used as an adjunct; guard against false reassurance if other clinical signs do not support a good read-out from the pulse oximeter. It is important to realize that there is often a time delay of a few seconds before the oxygen saturation registers; the true oxygen saturation in the patient's arterial blood may be lower than the reading suggests. Conversely, a low reading may relate not only to a patient's low oxygen levels but can occur in hypothermia, severe shock or if there is poor contact with or interference from the sensor.

In severe hypoxia, expect to see skin pallor due to vasoconstriction. Cyanosis is a late and highly ominous sign. In a child without an underlying cardiac condition it is extremely serious, suggestive of severe respiratory compromise; if due to hypoxia it suggests that the child is close to a respiratory arrest.

The circulatory system (C)

After airway and breathing, circulation needs to be assessed next. One of the first signs is the pulse rate, measured either by palpation (better centrally via a larger artery such as one of the carotid or femoral arteries) or with pulse oximetry (again, bearing in mind its limitations). Normal ranges of pulse rate can be seen in Table 3.1, varying with age. Tachycardia will often be seen in shock, where a decreased stroke volume (amount of blood pumped from the left ventricle in a beat) leads to release of catecholamines such as adrenaline. Bradycardia is a late sign of impending cardiac arrest. Weak pulses, particularly centrally, can be a sign of very poor perfusion as blood pressure is usually maintained until severe shock develops. Blood pressure readings are not as useful because systolic blood pressure is usually well maintained in a shocked child. Once hypotension has supervened, a cardiac arrest is highly likely.

Capillary refill is a much earlier sign of circulatory compromise. This should be assessed centrally, ideally on the sternum, where digital pressure is applied to the skin for 5 seconds and then released. The resultant blanched skin colour change should usually return to normal within 2 seconds. If this is prolonged, it is a sign of poor skin perfusion but is also suggestive of potential underlying poor perfusion to other organs. Although fever does not affect this sign (which is therefore very useful in assessing a child with septic shock), a cold environment does, so the ambient temperature needs to be taken into account.

Other signs of poor circulation relate to the effects on other organs. The skin can show obvious changes such as cold peripheries but also mottling. Poor perfusion will affect the conscious state and cause reduced urinary output and increased respiratory rate.

The central neurological system – disability (D)

A formal assessment using the Glasgow Coma Scale (GCS) used in adult patients is often very difficult to transfer over to a child. A quick way of assessing the conscious level in a child is using the acronym AVPU to signal progressively decreasing conscious level:

- **A**lert
- responds to **V**oice
- responds to **P**ain
- **U**nresponsive.

If the child in unresponsive to verbal stimulus but does respond to painful stimulus, this would equate to a GCS of 8 or less. Ways to measure response to painful stimuli can be to exert pressure over key points of the body, such as the sternum or supraorbital ridge. Subsequent sounds, localization to the painful stimulus or seeing if the eyes open can then be recorded.

Observing the posture of the child can be helpful. Often, hypotonia ('floppy' child) is present if the child has had a significant neurological insult. Sometimes there are specific positions a child will adopt depending on the location of intracranial pathology. Flexed arms and legs is known as a decorticate posture and extended arms and legs is known as a decerebrate posture, which is usually in keeping with a more severe injury. With meningitis, there may be neck stiffness.

The reaction of the pupils to a light stimulus can reveal important information related to the function of the central neurological system. Dilated pupils, or pupils that are unequal or unresponsive to light, may point toward serious neuropathology.

There may also be signs of abnormal central neurological function in the respiratory and circulatory systems, with altered breathing patterns, hyperventilation or apnoea. Brain herniation can cause a vasopressure response with hypertension and bradycardia.

Exposure (E)

A full assessment of the sick child involves stripping the patient down to look at the skin for bruising related to injury or rashes related to infection or allergy, which may dictate the need for investigations such as blood cultures, CT imaging and lumbar puncture (provided there is no evidence of raised intracranial pressure). It is also important to check the temperature and reassess all the signs again such as respiratory rate, pulse rate and so on.

With this simple but highly effective order of assessment, using airway, breathing, circulation, disability and exposure (ABCDE), the correct priorities are set to ensure that important features in the recognition of the sick child are not missed.

EARLY MANAGEMENT

Following the structured approach of assessing a seriously ill child, resuscitation and treatment is required. This follows the same systematic format.

Airway

Suctioning of secretions, removal of intra-oral foreign bodies or debris, a chin lift and jaw thrust are the immediate measures to free the airway. This is likely to overcome any oropharygeal obstruction. If the airway obstruction is not resolved by such simple manoeuvres, an **adjunctive airway** may be required. This may be in the form of a nasopharyngeal airway (NPA), an oropharyngeal or 'Guedel' airway or a laryngeal mask airway (LMA). If the airway cannot be maintained by one of these measures, endotracheal (ET) intubation will be needed. This could be via the nose (nasotracheal) or mouth (orotracheal). Externally, a tracheostomy can be formed, or in a dire emergency situation a cricothyroid puncture.

Nebulized adrenaline and intravenous steroids such as dexamethasone may all help to improve upper airway obstruction (see Chapter 28, Stridor).

If an airway foreign body is likely and the child is *in extremis,* then immediate transfer to an operating theatre for removal of the object using a ventilating bronchoscope can be life-saving. An oropharyngeal foreign body may need to be immediately engaged and removed with Magill forceps.

Breathing

Once the airway is secured, breathing needs to be efficacious. This requires there to be no intra-cerebral compromise of the respiratory centre and no abnormality of the lungs or musculature surrounding the lungs. Emergency treatment to aid breathing would be by applying high-flow oxygen via a facemask with a reservoir bag, or direct attachment to an endotracheal tube if the child has been intubated. Bag-valve ventilation ('bagging') can also be performed and works by introducing positive pressure. Investigations may include a chest radiograph, arterial blood gases or blood cultures, but stabilizing the airway and ensuring the child is breathing safely is by far the highest priority.

Circulation

Supporting and reversing inadequate circulation requires intravenous cannulation and administration of intravenous fluids in the first instance. However, if intravenous cannulation is not readily achievable, particularly in hypovolaemic shock where peripheral venous access may be difficult due to vasoconstriction, intra-osseous access will be required. Intra-osseous fluids can be infused effectively to reverse a circulatory deficit in children. Replacement of blood in the presence of significant blood loss may also be needed. Primary investigations are blood tests in the form of a full blood count, urea and electrolytes, clotting screen and a group and save/cross match. An electrocardiogram is also needed. If septic shock is suspected, blood cultures and intravenous antibiotics are required.

Disability

Rapid assessment using the AVPU stimulus test above will help ascertain if intubation is necessary to protect the airway. A child with responses only to painful stimulus or a child who is unresponsive (**P,U**) meets this criterion. Any patient with a neurological deficit must have their glucose level checked (don't ever forget glucose – **DEFG**). If blood glucose levels are found to be abnormal, they can be reversed with intravenous treatments. Seizures or convulsions can be treated with benzodiazepines. Signs of raised intracranial pressure are likely to require CT scanning and specialist input from neurology or neurosurgical teams.

Adequate analgesia – including the use of opioids where safe and appropriate – is an important part of the early management of the sick child.

Exposure

Septicaemia may cause a purpuric rash. Meningitis may cause a non-blanching purpuric rash, along with other signs of meningism. Intravenous antibiotics are then needed immediately. Anaphylaxis may cause an urticarial rash and angio-oedema, particularly around the lips and oropharynx. In such cases, adrenaline given via nebulizer and intra-muscularly is often immediately helpful, with intravenous steroids and intra-muscular antihistamines later on in the resuscitation period.

SAFE TRANSFER

Once the seriously ill or injured child has been appropriately resuscitated and stabilized, the next step in their care may involve some form of transfer to another hospital unit. Inter-hospital transfer will be needed if the level of care or expertise cannot be delivered at the first location where the child is seen. Reasons for this may include the need for specialist teams such as neurosurgery for intra-cerebral complications, paediatric ENT surgery for complex airway issues such as foreign body inhalation or laryngeal stenosis or even because of a lack of available facilities and staff within that hospital's intensive care unit. Wherever the destination or whatever the indication, the principles remain the same.

Resuscitation as described earlier needs to have taken place prior to transfer. It is essential to have good teamworking and communication throughout the whole process. From an ENT viewpoint this may require securing the airway jointly with the anaesthetist and could even mean a tracheostomy or cricothyroidotomy in an extreme airway emergency, although nowadays this is very rarely needed. Urgent treatment should not be delayed waiting for transfer or for a retrieval team to arrive. If endotracheal intubation is required and achieved, one of the

greatest concerns would be accidental displacement or dislodgement and it is essential that endotracheal tubes and tracheostomy tubes are carefully secured.

The principles of safe transfer have been refined by guidance from the Paediatric and Neonatal Safe Transfer and Retrieval (PaNSTaR) group[3] who, following the lead of APLS, have created the acronym **ACCEPT** to help focus thinking around safe transfer:

- **Assessment:** Before making a transfer a formal assessment needs to be undertaken by the transfer team. Continuous monitoring and reassessment will also be required.
- **Control:** The one in overall charge of the transfer needs to take control of identifying and allocating key tasks.
- **Communication:** Good communication between the current, transfer and receiving teams needs to take place, along with the child's family.
- **Evaluation:** Ensure that the transfer is appropriate.
- **Preparation and packaging:** Ensure appropriate preparation of the child, equipment and personnel has taken place, mindful of the limitations when providing medical care in a mobile setting.
- **Transportation:** The mode (road or air) and effects of that mode of transport to medical care need to be fully considered.

'Retrieval' teams are an increasingly important part of networked care for children. Teams may include paediatricians, anaesthetists, intensive care physicians, nurses and paramedics and a paediatric otolaryngologist. These teams have particular training needs including ongoing attention to maintaining their skills, and the otolaryngologist will often have a key role in the team.

PAEDIATRIC INTENSIVE CARE

Paediatric critical care describes the care of children who need an enhanced level of observation, monitoring or intervention which cannot safely be delivered in general wards.[4] Paediatric intensive care unit (PICU) staff look after children and young people whose conditions are life-threatening and who need constant close monitoring and support from equipment and medication to restore/maintain normal body functions. This includes care of children requiring intubation and ventilation, single- or multiple-organ support and continuous or intensive medical and nursing supervision. This also includes routine planned post-operative care for surgical procedures and during some planned medical admissions.

Three levels of such care are now widely accepted:

- **Level 1 Basic critical care:** A child, for example, with mild upper airway obstruction needing nebulized adrenaline would be managed here.
- **Level 2 Intermediate critical care:** This includes care of a child with an NPA, and early care of children with a newly fashioned tracheostomy. A level 2 unit (often referred to as a high dependency unit or HDU) would usually manage a child needing non-invasive ventilation such as CPAP.
- **Level 3 Advanced critical care:** This is often referred to as a paediatric intensive care unit (PICU). Such a unit would have a high ratio of nurses to children and be able to provide mechanical ventilation, in addition to other forms of organ support.

Cross-specialty working between ENT surgeons and PICU is essential in the care of critically ill children. Examples include post-operative management of a child after upper airway surgery, acute management of the difficult airway, acute upper airway obstruction, diagnosis and management of upper or lower airway malacia and multispecialty working for establishing and maintaining long-term ventilation (LTV) in patients with severe respiratory disease.

Strategies used in PICU are aimed at restoring and maintaining normal body functions. In essence, this is done by providing adequate oxygen and energy supplies to all organs and tissues to maintain their function. Oxygen is delivered to the body via respiration and delivered to the tissues by being carried in the blood (mostly via haemoglobin) and so normal tissue function is dependent on adequate oxygen supply to the lungs (ventilation) and adequate blood supply to the tissues (cardiac output and circulation). The principles of ventilation are largely generic, regardless of the large variety of underlying pathologies leading to the child needing ventilation. Ventilation ensures adequate pulmonary oxygen supply and carbon dioxide removal, but it may cause injury to the lungs by barotrauma/volutrauma and alveolar collapse, or by direct oxygen toxicity. Regardless of whether the lungs are normal or diseased, a 'lung-protective' ventilator strategy should be used. Pressure, volume and oxygen settings can be minimized and mild or 'permissive' hypercapnia and hypoxia is now accepted. In PICU PIP (peak inspiratory pressures) ≥30 cm H_20, expiratory tidal volumes ≥10 mL/kg and inspired oxygen concentration (FiO_2) ≥60% are all associated with ventilator-induced lung injury.

PICANet (Paediatric Intensive Care Audit Network) reports indicate that around 40% of admissions in the UK are planned (34% post-surgery) and 60% are for unplanned emergency care. The top three indications for admission to PICU are cardiovascular (28.6%), respiratory (26%) and neurological (11%). Around 65% of admissions require invasive ventilation and 15% non-invasive ventilation. PICU mortality rates remain low (<4%).[5]

If a child in PICU has signs of inadequate cardiac output (e.g. low blood pressure, evidence of poor perfusion, decreased urine output), this can be supported in a number of ways. It may simply involve restoration of intravascular volume (either with i.v. fluids or blood/blood products) or additional support with drugs that increase cardiac output. Inotropes (e.g. adrenaline) increase myocardiac contractility and heart rate; vasopressors (e.g. noradrenaline/vasopressin) increase systemic vascular resistance (e.g. in vasodilatory shock). Lusitropes (e.g. milrinone) aid diastolic relaxation of the heart so that it will contract better (Starling's law) and cause peripheral vasodilation increasing blood supply to the tissues.

Other therapies available in PICU replace the function of acutely injured organs in the short term until they recover or in the longer term until a more definite therapy option is found. Examples of this are total parental nutrition (TPN) and continuous renal replacement therapies (dialysis).

While maintaining/restoring normal function using the above strategies it is important to treat the underlying condition (e.g. antibiotics for infection, surgical intervention), keep the patient comfortable using sedation and analgesia if required, and ensure the patient's safety by preventing hospital-acquired harm and delivering high-quality care at all times.

For the very seriously injured/ill child in whom usual PICU therapies are not restoring or maintaining normal cardiac or respiratory function, but in whom the underlying condition is considered to be reversible, the use of extracorporeal life support (ECLS) strategies should be considered. Extracorporeal life support is a general term to describe prolonged but temporary support of heart and lung function using mechanical devices. Device applications require a combination of vascular access catheters, connecting tubing, a blood pump, a gas exchange device (oxygenator), a heat exchanger, measuring and monitoring devices, and systemic anticoagulation.

There are various subtypes of ECLS (with varying degrees of overlap) including:

- ECLA – extracorporeal lung-assisted systems
- ECMO – extracorporeal membrane oxygenation: a high-flow ECLS to replace lung and/or heart function, the term used synonymously with ECLS
- $ECCO_2R$ – extracorporeal carbon dioxide removal
- ECPR – extracorporeal cardiopulmonary resuscitation (emergency cardiac support in cardiac arrest).

The principle of these techniques is that blood is drained from the circulation and reinfused back after passing through the extracorporeal circuit where it is oxygenated and carbon dioxide is removed.

These are highly specialized techniques available only in a few designated centres.

MONITORING AND RECORDING

A child's medical condition can change very quickly; a previously 'well' child can become very ill in a short space of time. Careful monitoring and recording of simple physiological measurements such as pulse and temperature can alert staff early that a child is becoming dangerously ill, and may prompt early life-saving intervention. If parents or nursing staff feel a child has deteriorated, that in itself should be enough to prompt a careful medical review. There has been increasing emphasis on 'paediatric early warning scores' (PEWS) in recent years[6, 7] and most hospitals now have policies and protocols that guide staff on the need for a rapid response. There is no universally agreed PEWS system, so for now clinicians will need to familiarize themselves with the system in use in the setting in which they work. The important issue for doctors looking after children – particularly doctors who are less familiar with paediatric practice – is to be aware of the need to seek specialist advice if in any doubt.

RECOGNIZING 'SEPSIS'

Children may develop a life-threatening, rapidly progressive, exaggerated inflammatory response to infection, leading to impaired organ function. This has come to be known as 'sepsis' and has been the subject of much attention in recent years.[8, 9] There is a significant mortality (25%). Children at particular risk are the very young (infants under 1 year), those with a history of recent trauma including surgery, children with immune dysfunction and children with indwelling medical devices such as lines and catheters.

Whenever a patient presents with symptoms or signs raising the possibility of infection, sepsis should be considered. It is a time-critical emergency and warrants immediate intervention with completion of the 'sepsis six' within an hour, shown in **Box 3.1**.

BOX 3.1 The 'sepsis six' (NICE guidelines)[9]

1. High-flow **oxygen** via facemask
2. Blood **investigations** including blood culture (ideally before antibiotics) and blood gas
3. **Antibiotics** – broad-spectrum, intravenous (or parenteral) according to local guidance and taking account of patient's microbiology, given at maximum recommended dose within an hour of recognition of sepsis
4. **I.V. fluid** bolus – if signs of fluid depletion (including raised lactate)
5. **Lactate** measurement – repeated regularly if raised (>2 mmol/L)
6. **Fluid balance** monitoring

CHILD PROTECTION

Every professional involved in the care of children needs to be aware of the potential for children to be subject to abuse or neglect.

This can take the form of physical, emotional, or sexual abuse and may be perpetrated by family members, by friends and acquaintances or by professionals who come in contact with the child. Professional regulatory bodies – e.g. the General Medical Council (GMC) in the UK – expect doctors working with children and young people to be especially conversant with the features of abuse and neglect and to act upon any concerns they have.[10] Arrangements for raising such concerns vary in different healthcare settings and in different jurisdictions but the principles are essentially the same.

You should be familiar with the main presentations in your area of practice that can be caused by abuse and with the strategy for seeking appropriate advice and support.

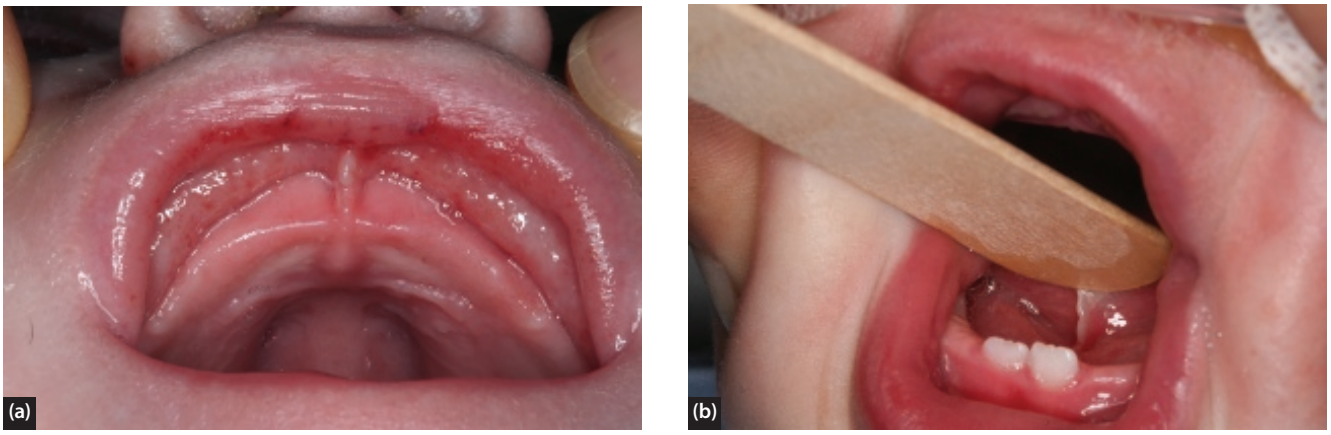

Figure 3.1(a) Tear of the labial frenulum with ulceration of the labial mucosa, **(b)** healing tear of the lingual frenulum.

Most children's hospitals will have a 'child protection' team who can be contacted for advice in confidence. Anecdotal evidence would suggest that few ENT surgeons make a diagnosis of child abuse, but it is essential that they are aware of it as a possible explanation for some unusual presentations. Up to 75% of children who suffer physical abuse have injuries to the head and neck (**Figures 3.1a, b and 3.2**). Some ENT presentations that may be linked with child abuse are shown in **Box 3.2**. If you suspect that a child's symptoms may be due to abuse or neglect, seek advice from an experienced colleague. Most children's hospitals have a designated team headed up by a paediatrician 'child protection lead' who has the expertise and sensitivity to give advice and support to you as a concerned clinician, and where necessary to explore the issue with the parents. This is clearly an area where great sensitivity and delicacy are needed. An accusation of abuse or neglect can have devastating consequences for the child and family.

BOX 3.2 Some possible non-accidental injuries in the head and neck

Tears to the lingual frenulum
Bruises to the cheeks, lips, gums
Nasal injuries
Injuries to the pinna, especially 'pinch' marks (**Figure 3.2**)
Auricular haematomas
Traumatic perforation of the eardrum
Maxillofacial fractures
Dental trauma
Injuries to the palate, e.g. due to forceful feeding
Bruising to the neck

A very small number of parents deliberately bring about symptoms and signs of disease in their child in an attempt to gain attention from healthcare personnel. ENT examples include ear injuries, blocked tracheostomy tubes and deliberate smothering. This is a serious psychiatric condition (Munchausen Syndrome by Proxy) and needs urgent and expert management.

Figure 3.2 Bruising of the ear. 'Pinch' marks as seen on the upper aspect of the pinna are said to be pathognomonic of non-accidental injury.

A small number of children may, for various reasons, be best looked after outside their family setting, for instance by social services or the local authority. They may be placed in a designated care setting or with an alternative family (foster family). Arrangements will vary in different healthcare settings, but in general these children ('looked-after children', or 'children in care') need particularly vigilant medical attention. They will usually have a named social worker and close liaison with her/him is important in ensuring continuity of medical management, especially if they require surgery, investigations or repeat follow-up visits.

BEST CLINICAL PRACTICE

- Retrieval teams are increasingly important in paediatric care, and otolaryngologists may be key members of the team.
- Beware impending 'sepsis' in a child. It warrants immediate intervention.
- Be aware of the potential for children to be subject to abuse or neglect.

FUTURE RESEARCH

- ➤ Paediatric critical care is a recognized and expanding medical specialty, with the potential for ever better care and outcomes for very seriously ill children.
- ➤ Early warning scores for sick children are being harmonized with the potential for more widely accepted guidelines on early intervention for the sick child.
- ➤ 'Retrieval' of sick children and transfer to PICU is an increasingly important part of the work of specialized children's hospitals.

KEY POINTS

- Children who are apparently well can deteriorate very quickly.
- Biphasic stridor suggests severe airway obstruction.
- Bradycardia and cyanosis are ominous signs in a child with airway obstruction.
- Beware the stridulous child whose breathing becomes quiet – she may be close to cardiac arrest.
- Cross-specialty working between ENT surgeons and PICU is essential in the care of critically ill children.

CHAPTER 4

ANAESTHESIA FOR PAEDIATRIC OTORHINOLARYNGOLOGY PROCEDURES

Crispin Best

SEARCH STRATEGY

Data in this chapter are based on the author's personal bibliography of key papers on paediatric anaesthesia and on his extensive experience in clinical practice. The website of the Association of Paediatric Anaesthetists of Great Britain and Ireland (APA) http://www.apagbi.org.uk is a good source of information on guidelines and current best practice relating to anaesthesia in children.

INTRODUCTION

The purpose of this review of anaesthesia for paediatric otorhinolaryngology (ORL) procedures is not to produce a definitive text for the expert anaesthetist working in a tertiary centre; rather it is to give a flavour of the techniques and pitfalls associated with the specialty. Guidance on patient selection and pre-operative preparation is discussed and some aspects are considered in greater detail.

Paediatric ORL surgery covers a whole range of conditions from the apparently simple such as the insertion of grommets to complex airway reconstruction. Even simple cases need advance planning. Any treatment episode for a patient is a cooperative effort between all the professionals involved. Only if the team works together will optimum conditions be provided to treat each condition quickly and effectively. From the moment the patient presents, no matter how 'routine' the case may be, this principle must be foremost in the minds of all. In the case of the shared airway (vide infra), this is even more critical.

Once the patient has been diagnosed, assessed for surgery and anaesthesia and their procedure scheduled, there must be a briefing of all staff at the beginning of the session to ensure that all are fully informed of what is proposed, and that everything is required for full pre-, peri- and post-operative care. More complex cases may require detailed advanced planning.

If in doubt, discuss the case with the anaesthetists well in advance of the day of surgery.

PATIENT SELECTION

The reason why families attend an ENT clinic is to seek an opinion for treatment for their child. If surgery is planned, anaesthesia and peri-operative care is a vital part of this process. It is important that whoever sees the patient in clinic is aware of what aspects of the medical history the anaesthetist needs to know. This can be broadly broken down into problems resulting from the condition itself, and associated conditions – both congenital and acquired. These need to be considered in the light of what treatment is proposed.

ORL conditions of anaesthetic relevance

Patients with obstructive sleep apnoea may need special nursing care and present challenges for post-operative management (see Chapter 27, Paediatric obstructive sleep apnoea).[1]

Any patient presenting with stridor or other symptoms of airway obstruction will be a source of particular concern to an anaesthetist. These patients can cause huge problems on induction of anaesthesia and can potentially lead to that most acute of emergencies the

'can't intubate, can't ventilate' scenario. Preparation and planning will prevent most of these dramas.

Associated conditions

CONGENITAL

There are many congenital conditions that may need special consideration in a child undergoing a general anaesthetic. These range from the obvious ones affecting the airway directly, such as laryngotracheal obstruction, to conditions affecting the child's general health, such as myotonic, neurological or cardiac conditions. Sometimes more than one condition coexists, for example Down syndrome in which patients have abnormal tissues, neck instability with cardiac anomalies such as atrial or ventricular septal defects. Some conditions improve with age, for example Pierre Robin sequence or Goldenhar syndrome, as the micrognathia associated with both improves with age. Some get worse, for example Treacher Collins syndrome and the mucopolysaccharidoses such as Hurler syndrome.[2]

It is also useful to know in advance if the patient has any conditions such as attention deficit hyperactivity disorder (ADHD) that may influence behaviour (see Chapter 5, The child with special needs). Children with autistic spectrum disorders (ASD) need to be identified well in advance of surgery. Many struggle with disturbance of their routine and are best having surgery on a day admission basis, preferably first on the list and with early discharge so that they can get back to their normal surroundings as soon as possible.

ACQUIRED

These conditions will be what patients usually present with, for example subglottic stenosis after prolonged endotracheal intubation, laryngeal webs and recurrent respiratory papillomatosis. Knowledge of what caused the problem and what has been done previously makes anaesthesia less of a challenge.

Drug history

Children fortunately do not tend to be the victims of the polypharmacy that afflicts the modern elderly adult. It is useful to document drugs that affect the heart, lungs and nervous system so that we can ensure that long-term conditions continue to be treated. Several of these may directly affect the conduct of the anaesthetic, including beta-blockers, vasodilators and diuretics.

Nature of procedure

Many ENT operations are considered 'routine'. Procedures such as adenotonsillectomy and insertion of drainage tubes into the middle ear are the bulk of the operative work of a department and children undergoing this type of surgery will not ordinarily need any special anaesthetic considerations unless the patient has any of the associated factors outlined above, or unless they have significant obstructive sleep apnoea (OSA). Other procedures (e.g. microlaryngoscopy and bronchoscopy) may be considered 'routine' in a tertiary referral centre. Which children need to be discussed individually in advance of surgery will depend on the experience of the surgeon and anaesthetist and on what is done in that particular unit.

Where do we operate?

The surgeon assessing the patient needs to consider where the procedure should be carried out. This depends on the nature of the case, the experience and practice of the team and the peri-operative facilities available on site, including nursing care and the availability of ventilatory support. Some cases are best suited to a tertiary referral centre and, if in any doubt, the staff at these institutions will be pleased to discuss the case with any referring clinician.

More detailed planning

It may be necessary to involve other disciplines in the care of cases which are difficult in themselves (e.g. major airway reconstructions) or where the patient has significant comorbidities. It is the practice in our institution to have a multidisciplinary meeting once a month where surgeons, anaesthetists, intensivists, specialist nurses and any other disciplines necessary meet and discuss forthcoming cases in detail. In this way PICU and HDU beds can be booked in advance, and ward and anaesthetic staffing rosters can be planned.

If in doubt, discuss the case with the anaesthetists.

PRE-OPERATIVE ASSESSMENT

It is becoming common practice for children and their parents or carers to attend a pre-operative assessment clinic before any operative procedure. It should be borne in mind that attending hospital with a child is in itself disruptive for both child and family, so ideally the patient should attend the pre-operative assessment clinic on the same day that they are seen by the surgeon.

Pre-op clinics are typically conducted by an experienced and suitably trained children's nurse. At this clinic the staff can take a history, examine the child and help prepare them for the procedure. This may include the provision of written and illustrated materials, which the family can peruse at home. It should be emphasized that, useful though these leaflets can be, they are no substitute for a proper interview with the anaesthetist. Any material used should also be prepared in conjunction with the anaesthetic department in order to reflect current practices and guidelines. If any problems are detected at this clinic, there should be a prompt communication with both surgeon and anaesthetist to aid planning. It is pointless for a patient to attend such a clinic if they then present on the day with something which should have been dealt with earlier.

ADMISSION

Whether a patient is admitted on a day-case basis (ambulatory care) or for overnight stay depends on local policies, geography and the nature of the operation. Many hospitals now carry out tonsillectomy, adenoidectomy, microlaryngoscopy and bronchoscopy and other similar procedures on a day-case or '23-hour' basis.[3] Irrespective of the time the patient stays in hospital, several things must happen before the operation commences.

PREPARATION AND ANAESTHETIST'S VISIT

The patient's weight and temperature must be checked. This allows the calculation of drug doses and early warning of any infections that may be present. The operating surgeon must see the patient, obtain consent for the procedure if this has not already been done, and mark the site of the operation if appropriate. The anaesthetist will see the patient, check the patient's general condition and confirm their suitability for anaesthetic. Careful note will be taken of any infection, especially of the respiratory tract. An active symptomatic respiratory tract infection causes a large increase in anaesthetic problems and these children should have their procedures delayed for 2 weeks until they have recovered. The anaesthetist will also explain the induction of anaesthesia to the patient and family and deal with any concerns they may have. In addition, they will discuss the post-operative period, especially with regard to analgesia.[4]

Fasting guidelines

It is very important that the patient is adequately fasted for the procedure (Table 4.1). Nothing ruins the anaesthetist's day like the appearance of a wave of vomit coming towards the airway on induction of anaesthesia. Compliance with guidelines can be patchy; parents sometimes misunderstand instructions or for one reason or another do not give accurate information, so detailed questioning may be necessary.[5]

Premedication

Some patients may require 'premedication' to reduce anxiety. As all the commonly used agents are sedative, they are almost always contraindicated in any patient who has an obstructed airway for any reason. If one is to be used, it must be **only** on the expressed instructions of the anaesthetist performing the procedure. Anticholinergics are sometimes given to dry up secretions and militate against the bradycardic effects of volatile anaesthesia. It is not our practice to use them as we find that we have more problems post-operatively with patients being unable to clear sticky secretions. They are, however, always drawn up ready for use in an emergency. Local practices will vary according to anaesthetic preference.

As always, if in doubt, discuss the case with the anaesthetists.

TABLE 4.1 Fasting guidelines

Food/drink	Fasting time (hours)
Clear fluids*	2
Breast milk	4
Formula or cow's milk	6
Pastes and solids	6

* Clear fluids include diluting juice but NOT natural fruit juices.

ANAESTHESIA

Briefing

Any operation is a cooperative venture. Before any operating list is started, the full team must assemble and there must be a thorough briefing given where all members can discuss the cases of the day. This will ensure that the list is correct, treatment plans can be finalized and the availability and operability of any specialized equipment that may be necessary can be checked. This is in line with the WHO recommendations on surgical safety, which also include a checklist to be completed before every individual case is started (Figure 4.1).[6]

Basic principles

There are few occasions in anaesthesia and surgery where the surgeon and anaesthetist work so closely together as in paediatric ENT procedures. Many of these involve a shared airway, and it must be accepted that, in the case of any deterioration in the condition of the patient, the anaesthetist must be allowed instant and full access to the patient to deal with the immediate problem. The surgeon's role in this circumstance is to provide assistance to the anaesthetist, which may extend in life-threatening circumstances to the provision of an emergency surgical airway. It therefore follows that any surgeon undertaking an operating list that includes patients likely to need emergency care **must** be capable of performing such a procedure. Unlike the adult situation, cricothyroid membrane puncture on children is difficult and has a high failure rate irrespective of how it is done, so *in extremis* a surgical cricothyrotomy or tracheostomy may need to be carried out urgently.[7]

Technique

The choice of anaesthetic technique will be largely dependent upon the type of operation being performed, the nature of the patient and any specific requests from the surgeon to assist with the operation. The well-known anaesthetic triad of 'anaesthesia, analgesia and relaxation' can be obtained in a number of different ways. Similarly, whether the patient should breathe spontaneously or be ventilated and whether they should be intubated or not will be covered in 'Spontaneous respiration vs endotracheal intubation and paralysis' below.

World Health Organization

SURGICAL SAFETY CHECKLIST (FIRST EDITION)

Before induction of anaesthesia ▶▶▶▶▶▶▶▶▶ Before skin incision ▶▶▶▶▶▶▶▶▶▶▶▶▶ Before patient leaves operating room

SIGN IN

☐ **PATIENT HAS CONFIRMED**
- IDENTITY
- SITE
- PROCEDURE
- CONSENT

☐ **SITE MARKED/NOT APPLICABLE**

☐ **ANAESTHESIA SAFETY CHECK COMPLETED**

☐ **PULSE OXIMETER ON PATIENT AND FUNCTIONING**

DOES PATIENT HAVE A:

KNOWN ALLERGY?
☐ NO
☐ YES

DIFFICULT AIRWAY/ASPIRATION RISK?
☐ NO
☐ YES, AND EQUIPMENT/ASSISTANCE AVAILABLE

RISK OF >500 ML BLOOD LOSS (7 ML/KG IN CHILDREN)?
☐ NO
☐ YES, AND ADEQUATE INTRAVENOUS ACCESS AND FLUIDS PLANNED

TIME OUT

☐ **CONFIRM ALL TEAM MEMBERS HAVE INTRODUCED THEMSELVES BY NAME AND ROLE**

☐ **SURGEON, ANAESTHESIA PROFESSIONAL AND NURSE VERBALLY CONFIRM**
- PATIENT
- SITE
- PROCEDURE

ANTICIPATED CRITICAL EVENTS

☐ **SURGEON REVIEWS:** WHAT ARE THE CRITICAL OR UNEXPECTED STEPS, OPERATIVE DURATION, ANTICIPATED BLOOD LOSS?

☐ **ANAESTHESIA TEAM REVIEWS:** ARE THERE ANY PATIENT-SPECIFIC CONCERNS?

☐ **NURSING TEAM REVIEWS:** HAS STERILITY (INCLUDING INDICATOR RESULTS) BEEN CONFIRMED? ARE THERE EQUIPMENT ISSUES OR ANY CONCERNS?

HAS ANTIBIOTIC PROPHYLAXIS BEEN GIVEN WITHIN THE LAST 60 MINUTES?
☐ YES
☐ NOT APPLICABLE

IS ESSENTIAL IMAGING DISPLAYED?
☐ YES
☐ NOT APPLICABLE

SIGN OUT

NURSE VERBALLY CONFIRMS WITH THE TEAM:

☐ **THE NAME OF THE PROCEDURE RECORDED**

☐ **THAT INSTRUMENT, SPONGE AND NEEDLE COUNTS ARE CORRECT** (OR NOT APPLICABLE)

☐ **HOW THE SPECIMEN IS LABELLED** (INCLUDING PATIENT NAME)

☐ **WHETHER THERE ARE ANY EQUIPMENT PROBLEMS TO BE ADDRESSED**

☐ **SURGEON, ANAESTHESIA PROFESSIONAL AND NURSE REVIEW THE KEY CONCERNS FOR RECOVERY AND MANAGEMENT OF THIS PATIENT**

THIS CHECKLIST IS NOT INTENDED TO BE COMPREHENSIVE. ADDITIONS AND MODIFICATIONS TO FIT LOCAL PRACTICE ARE ENCOURAGED.

Figure 4.1 WHO Surgical Safety Checklist (from http://whqlibdoc.who.int/publications/2009/9789241598590_eng_Checklist.pdf6).

Equipment

In addition to the full range of anaesthetic equipment that should be present in all locations where anaesthetics are given, there are several features that should receive extra attention (**Figure 4.2**). Although any child when anaesthetized may have a 'difficult' airway, this is much more likely in a situation where the patient is being anaesthetized for the investigation of just such a condition. Although every theatre suite should have a difficult intubation trolley containing emergency equipment, there is a case for duplication of this provision where elective airway work is being done. Specific items may be a matter for personal choice, especially with regard to equipment such as types of laryngoscope blade, for example. Recent reviews[8, 9] have emphasized the need for training and a common approach to any problems.

As well as the more traditional endotracheal tubes and face masks, the use of the laryngeal mask has proved invaluable in some cases of the difficult airway. Once one of these is in place, if the airway needs to be secured further, a fibre-optic intubation can be performed through the mask using a guide wire and airway exchange catheter, and the laryngeal mask removed.[10] This kind of procedure is complex and ideally should be planned in advance.

In addition to the traditional range of anaesthetic laryngoscopes, the anaesthetist may also have recourse to a number of newer video and fibre-optic devices (**Figure 4.3**).[11, 12] To a large extent, which is to be used is a matter of personal preference, however it is important for every unit to choose only one, and become expert in its use during routine cases. An emergency is no time to learn how to use an unfamiliar piece of equipment.

'Can't intubate, can't ventilate'

This is a situation every anaesthetist dreads and, as mentioned above, the surgeon may be called upon to assist in obtaining an airway. **NEVER FORGET the option of waking the patient up. The case can then be planned for another time in the light of what has happened.**

Figure 4.2 Basic set of equipment for paediatric airway anaesthesia. Included are face mask with a soft seal, different types of anaesthetic laryngoscope, endotracheal tube and laryngeal mask, Guedel airways, Magill forceps and an intubating bougie.

Figure 4.3 McGrath videolaryngoscope. This is one of the more effective types of videolaryngoscope, enabling a view of the larynx when conventional methods may not be adequate.

Assistance

The anaesthetist must have a trained assistant. This may be an experienced operating department assistant or nurse or another anaesthetist. Irrespective of who this person is, they must be familiar with local policies and guidelines, have a good knowledge of the available equipment and how it is used, and have taken part in the pre-operative briefing.

POST-OPERATIVE CARE

There is little point in proceeding with complex anaesthesia and surgery if facilities do not exist to care for the patients post-operatively. The post-anaesthesia care unit (PACU) must be staffed to a defined level of competence, and there must be equipment available in the unit to deal with any emergency, including emergency drugs and an anaesthetic machine. More complex cases may require the services of a high dependency or intensive care unit. The basic rule is never to start a case unless you have the facilities to finish it. The Association of Anaesthetists of Great Britain and Ireland has published general recommendations for organization and staffing.[13] If an emergency case has to be done where appropriate facilities do not exist, the anaesthetic team must recover the patient. Patients should not be discharged from the PACU until the anaesthetist/recovery staff are sure that the patient is fully conscious, is appropriately hydrated, is not in pain and has had appropriate analgesia prescribed as well as full instructions to

the ward on post-operative care. A handover sheet, which can be filled out by staff, is very useful for this purpose.

When patients are discharged, they should be provided with information sheets particular to their procedure, containing contact details for the institution should they have any problems.[14]

NEVER start a new case until the last patient is safe.

SPECIFIC OPERATIONS

Tonsillectomy and adenoidectomy

This is probably the commonest operation performed by the ENT surgeon. Surgical options are 'cold steel' dissection, or the use of the coblator or harmonic scalpel systems. Anaesthetically, the choice of airway management is to use either an endotracheal tube (ETT) or a laryngeal mask airway (LMA). The ETT is more secure than an LMA and is easier for the surgeon to keep out of the way in placing a Boyle Davis gag. However, the LMA is quicker and easier for the anaesthetist to place. The choice will depend ultimately upon surgical and anaesthetic preference. It important never to compromise an airway merely for convenience's sake.

Another discussion is whether to admit these patients as day cases (by which is meant early morning admission and evening discharge) or for an overnight stay. This will depend upon local facilities, patient population and patient preference, among other things. Analgesia must be effective no matter what system is chosen. A useful review covers this subject in more detail.[15]

Antiemesis can be helped with dexamethasone,[16] ondansetron or a combination of the two. Remember that patients can swallow a little blood during the operation, which can often lead to a vomit afterwards. This is of no consequence if small and not repeated.

Post-operative analgesia in our institution is provided by regular oral ibuprofen, with paracetomol as required. We do not give any form of oral opiate as a take-home drug; instead, patients are asked to contact us if they have any problems.

Airway examination and treatment

There is no doubt that the treatment of a compromised paediatric airway is one of the most challenging procedures to face any operative team, particularly for the anaesthetist. Not only will the patient have to be kept safe, but also there is little point in the child having an anaesthetic unless the surgeon is able to do the procedure. Safety is paramount. Surgery will not proceed until the anaesthetist is satisfied that the patient is in a fit state for that to happen. It **must** be remembered that waking the patient up again if the airway cannot be adequately secured is always an option. Recent reviews have emphasized the importance of training and a considered approach.[17, 18]

Patients will present with a variety of conditions, both congenital and acquired, which will be covered in other chapters of this book.

SPONTANEOUS RESPIRATION VS ENDOTRACHEAL INTUBATION AND PARALYSIS

The basic principle of paediatric airway anaesthesia is to keep the patient breathing. This sounds almost too obvious to state, but it must be remembered that all anaesthetic agents of whatever type depress respiration and reduce muscle tone such that a patient who, when awake, is capable of maintaining their own airway promptly loses it when anaesthetized. Additionally, in some cases such as mediastinal tumours the patient may be impossible to intubate in an emergency, making rescue very difficult if they have a respiratory arrest. A careful gas induction using sevoflurane in oxygen is the preferred method for anaesthetizing these patients. The airway is being constantly observed as the patient becomes anaesthetized and the process is gradual and controllable. Intravenous access, if not gained beforehand to avoid upsetting the patient, can be gained as soon as possible and the airway is under constant control.

Unlike the adult situation where the bulk of examination is for tumour or infection, the majority of paediatric patients present with disorders of breathing requiring further investigation. If they are intubated and paralysed, tracheo- or laryngomalacia may not be seen due to the pressure effects of insufflated gas. Similarly, if the patient is intubated for ventilation, the pressure of the endotracheal tube may squash pathology such as tracheal haemangiomata, making them impossible to see.

The ideal situation for both diagnosis and treatment of airway problems is the spontaneously breathing patient maintaining their own airway. This can be achieved either by using a volatile anaesthetic agent in oxygen or by the use of total intravenous anaesthesia (TIVA). Whichever method is used depends upon anaesthetic and institutional preference.

The use of a volatile agent has the benefit of simplicity in that the patients control their own depth of anaesthesia. If they become 'light', they breathe up and get deeper; if 'deep', the respiratory rate slows down, thereby lightening the anaesthetic. TIVA can be quite labour-intensive, as the rates of the infusions may have to be constantly adjusted according to circumstance. This takes the anaesthetist's attention away from the airway at what may be a crucial time.

The larynx is also sprayed with lidocaine to decrease the response to instrumentation, although care must be taken to ensure the patient is anaesthetized deeply enough to avoid temporary laryngospasm when this is done. Oxygenation can be obtained by means of a nasal airway attached to an Ayres 'T' piece anaesthetic circuit. If the patient is to be ventilated, they are better intubated. Jet ventilation, frequently used in adults, carries significant risk of barotrauma in small children although some centres use it successfully.[19] This is not our practice, as we believe the disadvantages far outweigh any benefits. Finally, a dose of dexamethasone is given to patients to try to reduce any oedema that may affect the airway post-operatively. The evidence for this is scanty but most experienced airway anaesthetists feel that this is of value.[20]

In summary, a logical approach with a high degree of safety is a gas induction of anaesthesia with sevoflurane or halothane (if available) in oxygen, the establishment of intravenous access if not already present, getting the patient deep enough to spray the larynx with lidocaine and the nose with xylometazaline, and maintenance of anaesthesia with spontaneous respiration using insufflated volatile with oxygen via a nasal airway. This has the added benefit of leaving instrumentation of the airway to the surgeon, as the anaesthetic has not affected the airway appearance.

Once the patient is stable on the operating table, any surgical examination and intervention can take place.

Micro-laryngoscopy and bronchoscopy

Examination of the airway is essential to diagnosis and treatment. There are a variety of methods including suspension laryngoscopy, examination with a Hopkins rod and bronchoscopy.

Suspension laryngoscopy is used for detailed examination of the larynx and associated structures (**Figure 4.4**). Great care must be taken not to overextend the neck, especially with conditions such as Down syndrome where there is a pre-existing instability. The mechanical advantage of the wheel used to adjust the suspension is enormous; the anaesthetist must watch this closely and stop the surgeon if the neck is moved too far.

The bronchoscope has a side arm for the attachment of the anaesthetic circuit and the delivery of gases (**Figure 4.5**). It also has side holes along the shaft to allow ventilation of both lungs when the instrument has been passed down one bronchus. When the surgeon first places the instrument, it must be passed down to the carina or these side holes may still be in the pharynx, preventing proper ventilation and control of the airway.

At every stage of the examination the surgeon must check with the anaesthetist that the patient is stable and well oxygenated. Communication is key; there must be a constant dialogue between the two. During any examination the anaesthetist must ensure that, when the surgeon is assessing the airway, the patient is not subjected to any degree of positive pressure from the anaesthetic circuit. This may distend the trachea or bronchi and make airway collapse much less apparent. However, positive pressure can be applied on demand to assess how much a collapsed airway can open.

Removal of airway foreign body

The approach here is the same as above, except that grasping forceps may be used either on their own with the aid of a Hopkins rod or through a bronchoscope. The preferred method is to have the patient breathing spontaneously as some feel that positive-pressure ventilation may force bits of the object further into the respiratory tree and the paralysed patient will, by definition, have periods of apnoea when examination and retrieval are taking place. However, jet ventilation can be used as long as the astute anaesthetist is aware of potential problems.[21]

Laser surgery

Laser surgery is covered in more detail in a review.[22] Safety is the prime consideration, and the laser must never be used unless staff are properly trained in its use and all appropriate precautions are taken.

Reconstruction of the airway

There are a large number of procedures that can be carried out for reconstruction of the airway, ranging from a cricoid split to full tracheal reconstruction under cardiopulmonary bypass. The principles, however, are exactly the same as above, i.e. scrupulous attention to the airway and good communication with the surgeon. If we take the example of an anterior laryngotracheal graft, the procedure may be as follows.

Figure 4.4 Laryngoscope and suspension. This illustrates the lever formed by the laryngoscope with the arm of the suspension system. The wheel at the top, which is used for adjusting the extension and flexion of the head on the neck, has a considerable mechanical advantage and damaging overextension could result.

Figure 4.5 Bronchoscope. Note the side holes towards the end of the 'scope, and the plastic mount for attaching the anaesthetic 'T' piece. This one is prepared for laser surgery, with a Hopkins rod and YAG laser fibre *in situ*, which reduces the bore of the system considerably, making it even more important to keep gas leakage as low as possible.

Pre-operatively the patient is breathing normally, albeit partially obstructed. In this case the patient will be orally intubated with a smaller than normal-sized ETT. The surgeon will then make a tracheostome for the duration of the operation through which the anaesthetist will ventilate the patient, and the patient will then have a nasal ETT placed at the end of the procedure. The tip of the ETT can be positioned under direct vision by the surgeon before the tracheal incision is closed. The patient remains intubated for some days post-operatively, with the head in a neutral position to allow time for the trachea to heal.

Tracheostomy

A paediatric tracheostomy differs from the adult in technique, as a vertical slit is made in the trachea after placing two lateral support sutures. Anaesthetic technique will depend upon why the patient is having the procedure. A stoma for a patient who requires one for chronic ventilation is very different from one who is undergoing the procedure for an acute airway problem. The anaesthetist, who may have to sit at the head of the patient manually supporting the airway, must guide the surgeon. Once the surgeon has identified the trachea and made a vertical slit, the endotracheal tube will be slowly withdrawn under direct vision until the tracheostomy tube can be inserted.

Post-operative care is key; the stay sutures remain in place and are stuck to the chest with tape while a track forms. This will enable a replacement tube to be placed in the event of the first one being displaced or falling out.

Ear operations

GROMMETS

The commonest operation and one of the simplest. Beware this illusion. The patient is still fully anaesthetized and asleep is asleep. The anaesthetist will probably use a laryngeal mask airway. The surgeon must check that the patient is fully prepared before starting: a myringotomy is highly stimulating and the patient suddenly moving as the incision is made could be disastrous.

MIDDLE AND MAJOR EAR OPERATIONS

The requirement seen in adult surgery for induced hypotension during the procedure is not necessary in children. Children have a lower resting blood pressure than adults, and modern anaesthetic agents can produce a good operating field for the surgeon without recourse to beta-blockers or vasodilators. Placing the patient a little 'head up' to reduce venous pressure and ventilating the patient to normocapnia is often all that is necessary. The use of nitrous oxide is a little more controversial: some believe it increases the pressure in the middle ear, some that it makes no difference, and evidence can be found in the literature for both positions. Ultimately, this is a question of operator preference and should be discussed with the anaesthetist beforehand.

Nasal surgery

ADENOIDECTOMY

Adenoidectomy is either a single procedure or carried out in conjunction with the placement of grommets and/or tonsillectomy. Again, the choice of how to maintain the airway is a matter of discussion between surgeon and anaesthetist.

REDUCTION OF NASAL FRACTURE

This ostensibly simple operation can be fraught with danger: the nasal bone may have to be refractured in order to get a good result and this can occasionally result in a torrential haemorrhage. The anaesthetist is best advised to use a laryngeal mask airway and place a throat pack before the surgeon proceeds. No one wants to have to deal with an unprotected airway rapidly filling up with blood.

Head and neck

This can range from a 'lumpectomy' to the excision of branchial or thyroglossal cysts. Operations common in adults, such as total laryngectomy, are fortunately extremely unusual in children. The anaesthetist will ensure that the airway is protected by placing an endotracheal tube. A laryngeal mask airway is not secure enough when the head is fully draped, as the head position may be changed during the procedure to improve surgical access.

KEY POINTS

- The airway must be protected at all times. If there is any problem whatsoever, the anaesthetist must instantly be given as much access as required.
- Good communication is crucial. Never start a procedure until there has been a full briefing of all involved staff. This is the time to plan for any problems, not when they occur.
- Never forget that the patient can always be woken up again, to come back another day. Do not persist in the face of adversity.
- Finally, if in any doubt, discuss the case with the anaesthetist.

CHAPTER 5

THE CHILD WITH SPECIAL NEEDS

Kate Blackmore and Derek Bosman

SEARCH STRATEGY

Data in this chapter may be updated by a Medline search using the keywords: special needs, cerebral palsy, disability, prematurity, neurodisability, Down syndrome, hearing loss, cochlear implant, obstructive sleep apnoea, laryngomalacia, tonsillectomy/adenoidectomy and aryepiglottoplasty.

INTRODUCTION

While the majority of paediatric otolaryngology deals with routine work in the well child, there is a significant part of the workload for the paediatric otolaryngologist that deals with children with special needs. The incidence and survival of very preterm infants has increased dramatically over the last few decades and with this comes increased morbidity.[1, 2] Children with special needs are prone to the usual childhood otolaryngological problems but they are also predisposed to specific problems mainly related to airway difficulties and hearing loss. The whole approach to treating a child with special needs is different and requires special consideration.

TERMINOLOGY

An **impairment** describes a pathological process (e.g. cerebral palsy) and a **disability** is the consequence of an impairment. A **handicap** is a disability of body or mind which interferes with the ability to lead a normal life or to benefit from a normal education.[3] Although terms such as handicap and disability are used commonly in the medical literature, they can be upsetting to parents, and doctors should be sensitive to this.

Special needs is an umbrella underneath which a diverse range of needs often caused by a medical, physical, mental or developmental condition or disability can be categorized. It can include cognitive difficulties, physical or sensory difficulties, emotional and behavioural difficulties, and difficulties with speech and language. This term seems to be more commonly acceptable to parents.

GENERAL CONSIDERATIONS

Hospital appointments

The clinical environment in which children with special needs are seen is important. The consulting room needs to be large enough to accommodate wheelchairs and equipment along with room for the carers.

It is paramount that these families are not kept waiting for long periods in the outpatient department as this can cause great difficulties and distress for the child. Child-friendly waiting areas and the presence of play therapists can help minimize distress and upset during outpatient consultations.

Ideally, hospital appointments should be kept to a minimum. Children with multiple comorbidities will see many different specialties, resulting in frequent trips to the hospital. The disruption to the child's routine can be significant. Specialist clinics that bring clinicians and allied healthcare workers together offer a great advantage to both the clinicians and the family, for example a tracheostomy clinic

bringing together ENT, respiratory paediatricians and speech and language therapists.

Clinicians should also not forget the cost implications of multiple hospital appointments. A recent cross-sectional study in the UK revealed that children with multiple comorbidities are more commonly born to families in the lower socioeconomic groups so that economic challenges may compound the difficulties of looking after a child with complex needs.[4]

Whether within a specialist clinic or not, the time required for an adequate consultation is significantly longer than for typically developing children without complex needs and multiple morbidities and this should be acknowledged when planning clinics and operating lists. Histories are more complex, examination is more challenging and discussions regarding treatment, particularly potential surgery, require more detailed explanation and planning.

Communication

Good doctor patient/parent communication has been shown to result in improved patient knowledge, better adherence to treatment, decreased surgical morbidity and greater satisfaction with care.[5, 6] This is especially true when treating children with special needs. Good, clear communication with the parents/carers, the child and any healthcare professionals involved with the child is paramount.

PARENTS/CARERS

In assessing children with complex problems it is often tempting to used closed questioning to control the duration of the consultation. Parents perceive this approach as showing a lack of interpersonal interest and ultimately it will result in a suboptimal consultation. Parents have greater trust in doctors who allow them to tell their whole story, express their concerns and listen to their ideas.[5, 6]

Parents of children with multiple comorbidities or complex problems will be 'experts' in their children and want, rightly, their views and concerns to be addressed in any decision-making. Decisions about care and management should be part of a family-centred process in the majority of cases.

It is also important to recognize that the parents' priorities for their child may not reflect your own. For example, parents of a child with a tracheostomy may be keen for early decannulation, or conversely may be reluctant to consider decannulation as they are nervous about losing the security of what they perceive as a 'safe' airway.

Parents commonly report that doctors do not give enough information with regard to their child's surgery or health status, particularly in the context of chronic or terminal illness.[5, 6] While we may feel that we have covered all the essential information in explaining, for example, a surgical procedure, its complications and recovery time, it is some of the more minor points that can be important to the parents: how much hair will be removed, the site of the intravenous cannula, how long until their child can eat. In children with special needs these seemingly minor issues can be particularly important and it is essential that the doctor takes the time to answer all the parents' questions.

PATIENT/CHILD

Children should be involved in as much of the consultation as possible. They should be given information in a way they can understand it, given choices about their care and asked their opinion. Children will often understand more than has been assumed.[6] This was shown in Bluebond-Langner's study of terminally ill children in which children as young as 3 years were aware of their diagnosis and prognosis despite not being told by an adult.[7]

While involving the patient may be more difficult in a child with special needs, it is important that any child who has the ability to understand and process the information is given the opportunity to do so. Increased understanding will heighten confidence, decrease fear and improve the level of trust between the child and their parent/doctor. However, this has to be undertaken with the agreement of the parents – giving too much information may be severely detrimental to a child with special needs.

Again, where possible, understanding the child's priorities regarding their health care and what they deem to be important for improving their quality of life should not be underestimated.

COLLEAGUES

Children with special needs will often be under the care of many different specialties and it is vital that there is clear communication between everyone in the healthcare setting. All involved clinicians and allied healthcare workers should be copied in to letters from outpatient consultations and inpatient attendances. This clear communication ensures that everyone involved is aware of the child's current health status and treatment plans. It also allows for the potential coordination of multiple procedures under a single general anaesthetic (e.g. blood tests and tooth extraction), which will decrease the amount of undue stress on the child.

PROGNOSIS, PALLIATION AND QUALITY OF LIFE

Full discussion of this issue is beyond the scope of this chapter but it is important that we take time to consider some areas that we will have to address during our work with children.

The significant advances in neonatology over recent years have dramatically increased the survival of extremely premature babies.[8–11] There was a 44% increase in the number of extremely premature babies admitted to the neonatal intensive care units in the UK over the 10-year period from 1995 to 2006,[10] although evidence suggests that the long-term morbidity, particularly neurodisability,[9] of the survivors has remained unchanged.[10]

Because of the advances we have seen in neonatology, doctors are increasingly likely to have to make difficult decisions about whether to start or continue invasive life-sustaining treatment with the known risk of a poor long-term prognosis. Withholding or withdrawing life-sustaining treatment in a neonate, or indeed a child of any age, is extremely difficult and often highly charged and emotive. While advances in technology make it increasingly possible to sustain life, this may only increase pain and suffering to the child and their family. It is essential that the healthcare team has allowed enough time to gather information about the child's condition and other relevant problems before any discussions or decisions on whether further treatment is appropriate can be made.[3] Decisions should never be rushed.

The Royal College of Paediatrics and Child Health document *Withholding or withdrawing life sustaining treatment*[3] gives guidance on the circumstances when withholding or withdrawing treatment should be considered. The guidelines advise that, if the future life of the child will be 'impossibly poor', then it would be reasonable to withhold treatment. In a child whose life is already 'impossibly poor' and there is no sign that this will improve in the foreseeable future, then it would be reasonable to consider withdrawing treatment.

In situations where withholding or withdrawing treatment is deemed the most appropriate course of action, this should be discussed with the family at an early stage. The family must be given all the information they require, along with enough time to be able to understand and process it. They should also be given the opportunity to seek a second opinion if they wish. The consent of the parents is important for the final decision to be made, but the ultimate responsibility lies with the healthcare team. This may help lessen the guilt that some parents/carers feel following decisions in these situations.[3]

Reaching a decision to withdraw or withhold treatment does not mean cessation of care. The provision of palliative care to provide pain relief, alleviation of other symptoms (e.g. airway distress) and also support the emotional, social and spiritual needs of the child and their family is paramount.[3]

In situations where withdrawal of treatment is not appropriate but there is an expected progressive morbidity, communication with the family, and the child if appropriate, is again extremely important. When discussing prognosis and long-term morbidity, doctors have a tendency to 'medicalize' outcomes and list potential complications and morbidities with percentages of likelihood. While this is obviously an important area, it is imperative that the quality of life the child and family may have is discussed, including the capacity for happiness, and the good and the bad that go along with caring for a child with multiple comorbidities. The positive aspects of what life ahead may look like need to be considered; do not simply dwell on the potential problems.[12]

What makes a 'good quality of life' is a difficult philosophical question to which there would be no unanimous answer. Many people with severe functional limitations consider they have a life of high quality and are happy to be living it while an observer may not rate it so highly. Do those living with disabilities have a more positive view of their life because they have never known an alternative?[13] Do they find more value in things that able-bodied individuals value less?[14] Whatever the answer, it is important that we do not judge the quality of life of those with several functional limitations on the same basis as we view our own lives. Our priority should be to provide a high quality of care to children with disabilities and provide support for their families.

THE EAR AND HEARING LOSS

Hearing loss

Children with hearing loss who have additional disabilities make up a significant proportion of the hearing-impaired paediatric population and they can be a challenging group to manage. It is estimated that 2–4% of neonates in the neonatal intensive care unit will have a significant bilateral hearing loss.[15] The underlying cause for sensorineural loss is probably multifactorial, with risk factors such as low birthweight, low Apgar score, hyperbilirubinaemia, ototoxic medication and mechanical ventilation all being well documented.[16] It has also been reported that low birthweight babies often have central auditory processing problems, with difficulty discriminating speech and poorer auditory recognition than that of term neonates.[17, 18]

Hearing loss may also be conductive or have a conductive element to it. This is often seen in children with Down syndrome or craniofacial abnormalities, and it has been associated with ventilator-dependent children.[19]

Hearing loss is associated with delayed speech development and learning at school[20] so it is imperative that these children are picked up by audiological services at the earliest opportunity. In the past, children with multiple comorbidities have been overlooked with regard to improving their hearing simply because of the difficulty in obtaining accurate audiometry. Testing using auditory brainstem responses (ABRs) has allowed detection of hearing loss to be more accurately assessed in children with multiple problems.

Fitting of hearing aids at an early stage, regardless of neurological or mental status, has been shown to improve auditory behaviours in a significant proportion of children with multiple disabilities.[21] However, there will be a number that do not improve or simply cannot tolerate wearing the aids. There may also be difficulties fitting the aid in a congenitally narrow external meatus, or increased problems with wax impaction or recurrent otitis externa as a result of the mould.

Cochlear implantation in children with profound hearing loss and other disabilities was a controversial issue in the earlier days of implantation. There is increasing evidence that children with additional disabilities can benefit greatly from a cochlear implant.[22–26] This group of children may not achieve the same outcomes with regard to open set speech recognition as those with no other disabilities

but in the majority of cases they have improved speech perception and communication abilities.[22] Being able to predict the outcomes of surgery in children with additional disabilities is obviously much more difficult and parents must have realistic expectations of surgery.

Middle ear disease

OTITIS MEDIA WITH EFFUSION

Otitis media with effusion (OME) is common in the paediatric population and the associations with speech and language delay in early childhood and poor behaviour have been well reported.[27–29] Children with multiple disabilities are often already predisposed to language deficits and behavioural and learning difficulties.

Children with craniofacial abnormalities are more susceptible to OME due to the presence of a small nasopharynx and Eustachian tube anomalies, and there should be a heightened awareness when seeing these children.

Diagnosis can be difficult as examination is often challenging, particularly in the presence of wax impaction or anatomical changes such as narrow external canals in children with Down syndrome. If obtaining hearing thresholds with age-appropriate audiometry and tympanometry is not possible, it may be necessary to undertake ABR under a general anaesthetic. This would also allow any necessary ear toilet and thorough examination of the tympanic membrane/attic plus the insertion of ventilation tube if appropriate. Controversies regarding ventilation tube insertion in children with Down syndrome will be discussed in Chapters 6, The child with a syndrome and 13, Otitis media with effusion.

CHOLESTEATOMA

Cholesteatoma in a child with special needs is a difficult situation often requiring a general anaesthetic to confirm the diagnosis. Computed tomography (CT) of the temporal bone will aid planning of the surgical approach and identify and any anatomical variants. There is no single correct approach to surgery and each case has to be assessed individually. Open mastoid surgery has the advantage that, hopefully, only one surgical procedure is required and any residual disease will be visible on examination. However, open cavities often require regular aural toilet, particularly in the early post-operative period, and the child may not tolerate this. The family may also find keeping the ear dry difficult to achieve, and swimming may be an important part of the child's therapy.

Undertaking a combined approach tympanoplasty would avoid these problems but may require multiple surgeries to exclude recurrence, particularly as audiometric testing may not be possible as an observation tool. The associated comorbidities of the child, however, may make multiple general anaesthetics unviable.

Recent studies reveal that diffusion-weighted magnetic resonance imaging (MRI) of the temporal bones is becoming a useful tool for detecting residual and/or recurrent cholesteatoma. This technique is increasingly showing a high positive predictive value for detection of cholesteatoma and may reduce the number of second-look procedures in canal wall-up surgery.[30, 31] One drawback in paediatric patients with special needs is that it will almost certainly have to be undertaken under general anaesthetic.

THE UPPER AERODIGESTIVE TRACT

Children with complex physical comorbidities, particularly neurological, will frequently have respiratory problems and feeding difficulties. There may be a number of contributory factors which may have an overall cumulative effect.

Feeding, aspiration and gastro-oesophageal reflux

Oromotor skills are often dysfunctional in those with neuromuscular pathologies.[32–34] Children with cerebral palsy in particular may have difficulty coordinating swallowing with ventilation. The resultant 'turn taking', alternating between breathing and swallowing, can lead to aspiration of solids and fluids at mealtimes.[33]

Gastro-oesophageal reflux is also more common, and often more severe, in children with cerebral palsy or other neuromuscular disorders. The reason for this is unknown but it is hypothesized that it may be due to increased intra-abdominal pressure caused by the spasticity of the abdominal muscles. Altered peristalsis combined with dysfunctional oesophageal sphincters can then result in aspiration of refluxed material.[33]

Coughing and choking during feeding will draw attention to the possibility of aspiration, particularly when associated with recurrent lower respiratory tract infections, but often in children with comorbidities aspiration is silent.[33–35] While these children may struggle during mealtimes, they rarely show signs of aspirating.

The consequences of aspiration are also varied, with some children tolerating recurrent episodes with no sequelae. More commonly, recurrent aspiration results in lower respiratory tract infections, which may ultimately lead to lung fibrosis in severe and unrecognized cases. Diagnosing silent aspirators is more difficult and they often go unrecognized until malnutrition or respiratory complications occur.[34]

Treatment of aspiration ranges from positional/postural feeding positions and feed thickeners to tube feeding via a nasogastric tube or gastrostomy. Tube feeding has been associated with a higher mortality than in those fed orally but whether this is a result of the parenteral feeding rather than a reflection of the underlying comorbidities is not known.[36, 37] Tube-fed children are still at risk of reflux and aspiration even in those who have had a fundoplication at the time of gastrostomy.[38] Children with a tracheostomy appear to have some protection from the complications of tube feeding and this may be due to the ability to undertake regular suctioning, application of oxygen and nebulizer and positive-pressure ventilation.[39]

Obstructive sleep apnoea (OSA)

Children with craniofacial anomalies, Down syndrome and neuromuscular disorders are all at increased risk of obstructive sleep apnoea (OSA). With the multitude of other problems that this population of children may have, OSA is often overlooked or simply felt to be 'normal for him/her' by their parents/carers. Given the association with disrupted sleep, irritability and behavioural problems, failure to thrive and at the severe end of the spectrum pulmonary hypertension and right heart failure, it is vital that there is a high index of suspicion.

Predisposing factors may relate to anatomical abnormalities such as midface hypoplasia in the craniofacial disorders and hypotonia of the pharyngeal musculature in the neuromuscular disorders. In some cases (e.g. Down syndrome) it may be a combination of both. Other documented associations are seizure disorders, gastro-oesophageal reflux, increased oral secretions and obesity.[40, 41]

Management of OSA in children with complex problems should be undertaken in a multidisciplinary approach. Sleep disorder problems are common in this group of children and it is difficult to be assured of a correct diagnosis of OSA from clinical examination alone. Polysomnography is the gold standard for diagnosis and will aid in selection of children who are appropriate for surgical intervention.

Management should be undertaken in a stepwise approach, eliminating simple factors like bacterial or allergic rhinitis as a first line. Although in the general paediatric population over 80% of cases of OSA will be effectively treated by adenotonsillectomy alone,[42] the same cannot be said for those with additional comorbidities, particularly if there is a neuromuscular element.

Most would agree that the aim is to avoid a tracheostomy where possible and first-line surgical management of removal of the tonsils and adenoids, even if only mildly enlarged, is the general approach. Whilet adenotonsillectomy may not completely resolve the obstructive symptoms, it may allow the consequent use of a nasopharyngeal airway or continuous positive airway pressure (CPAP) to maintain an adequate airway.

The implications of anaesthesia in children with other comorbidities and the increased risks of complications following surgery need to be considered and any decision to proceed with surgery made within the multidisciplinary team. Parents should be counselled accordingly.

Other surgical approaches that have been shown to improve OSA in some circumstances but are rarely helpful in routine practice include uvulopharyngopalatoplasty,[43–45] mandibular advancement,[46] tongue base reduction and hyoid suspension.[44] Distraction osteogenesis may have a role in some children with craniofacial anomalies (see Chapter 19, Craniofacial anomalies).

The management of OSA in children with complex problems should not be rushed but it is also imperative in some circumstances to act early, for example if there is concern about impending pulmonary hypertension. Some disorders, such as the mucopolysaccharidoses, are progressive and delaying intervention may result in a lost opportunity.

Laryngotracheal disease

Stridor in children with multiple comorbidities may be multifactorial and/or multilevel. It is often simply, but incorrectly, attributed to the underlying neuromuscular problems associated with the child's diagnosis. Where possible, a flexible nasolaryngoscopy in the clinic will allow a dynamic assessment of the upper airway to the level of the vocal cords. There should be a high index of suspicion of multilevel disease, and a full airway assessment under general anaesthetic may be required.

When underlying airway pathology is found it must be remembered that children with complex comorbidities, particularly neuromuscular, often do not respond as well to treatment as an otherwise well child would be expected to. Laryngomalacia is a good example of this. While most cases of laryngomalacia do not require surgical intervention, for those that do supraglottoplasty has a high success rate.[47] Patients with comorbidities, however, tend to have a worse outcome.[48] Children with cardiac abnormalities have been found to have a significantly higher failure rate following supraglottoplasty, which may be related to respiratory rate, an increased work of breathing or associated developmental problems.[49] However, it is children with neurological comorbidities who do particularly badly with laryngomalacia, many requiring revision surgery[49–51] and a significant proportion requiring tracheostomy.[49, 52] This may be due to a difference in underlying pathophysiology in laryngomalacia associated with neuromuscular disorders. Rather than being due to overly pliable cartilage, the underlying problem is more likely due to laxity of the soft tissue of the supraglottis. This results in an excess of redundant soft tissue, which prolapses into the airway, and ultimately the underlying cartilage will also be involved.[53]

SURGERY IN THE CHILD WITH SPECIAL NEEDS

Undertaking surgery in a child with special needs requires careful consideration and planning. Multiple comorbidities may affect decision-making and sometimes a more conservative or aggressive approach is undertaken compared with what would be required in an otherwise well child. In some cases it may not be possible to undertake a full assessment of the child other than under a general anaesthetic. While it is certainly not a standard approach, in these cases decisions as to the surgical procedure may need to be made 'on the table'. This has implications for consent and often requires the surgeon to speak to the family while the child is under anaesthetic.

It is essential that there is a dedicated pathway for children admitted for surgery with special needs and that all involved specialties are aware of the impending surgery and admission.

Hospital admission and surgery in children with complex medical problems or learning disabilities are often associated with high levels of anxiety in both the patient and parent. In order to minimize distress it is imperative that communication, planning with the family and pain management are undertaken on an individual basis.

Children with special needs often have a very strict daily routine and alterations to this can cause significant distress. Trying to accommodate the child in a side room where possible will help avoid excessive noise disturbance and will make it easier for the parent to care for their child.[54] Where possible, having the child first on the theatre list will help reduce fasting time and the anxious wait for surgery.

Surgical pre-assessments enable the child and parent/carer to visit the ward and theatre complex prior to surgery and allow the family to familiarize themselves with the department. This may help decrease anxiety on the day of surgery and help highlight any potential problems prior to admission.

Anaesthetics can be challenging but assessment by the anaesthetist prior to admission will help prepare for a smooth patient journey. Sedative premedication may help settle the child prior to the anaesthetic and may aid with cooperation. It may not be possible to insert cannulae until the child is anaesthetized and these may need to be removed as early as possible after the procedure.

Pain management in children who are unable to express pain through the usual verbal or behavioural routes can be difficult, and standard approaches are often unhelpful. Parents often recognize specific signs when their child is in pain, such as change in vocalization, altered facial expression, change in usual posture and reduced responsiveness to stimuli.[55] These can often be very subtle findings that would be apparent only to the parent/carer who knows the child well. Health professionals need to work closely with the parents in assessing pain levels in order to be able to manage the child's pain appropriately.

Many of these children require a 'step up' of services when surgical procedures are undertaken, such as a high dependency unit bed post-tonsillectomy in a child with OSA and spastic cerebral palsy. It is also important, however, to try to discharge them home as soon as it is safe to do so. This will allow them to be in a more familiar environment and to return to their usual routine. In some situations it is preferable to discharge before all the usual criteria have been met (e.g. passing urine, eating).[56]

BEST CLINICAL PRACTICE

- ✓ Examination of a child with special needs can be difficult and it may be necessary to proceed to examination under general anaesthetic in order to gain a diagnosis.
- ✓ There is increasing evidence that children with additional disabilities can benefit greatly from cochlear implantation.
- ✓ Stridor in children with complex comorbidities may be multilevel and multifactorial.
- ✓ Obstructive sleep apnoea is often overlooked in children with complex comorbidities. Management should not be undertaken without careful consideration and planning, but some disorders are progressive and treatment needs to be undertaken without untimely delay.

KEY POINTS

- The survival of preterm babies has dramatically increased over recent years but the long-term morbidity has remained unchanged.
- Children with special needs require a more detailed evaluation which takes longer.
- Specialist clinics that bring together health professionals offer a great advantage to both the clinicians and the family.
- It is essential to ensure good communication with all the health professionals involved in the care of a child with special needs.
- Surgical outcomes are often less successful in the child with special needs than for other children.

CHAPTER 6

THE CHILD WITH A SYNDROME

Thushitha Kunanandam and Haytham Kubba

SEARCH STRATEGY

Data in this chapter may be updated by an OVID search using the keywords: Trisomy 21 (Down syndrome), Turner's syndrome, 22q11 deletion (velocardiofacial syndrome and Di George sequence), mucopolysaccharidosis, CHARGE and Pierre Robin, each of which was cross referenced with search term such as otolaryngology, airway, otology, larynx and nose.

INTRODUCTION

The subject of syndromes can be a confusing mess of eponyms, acronyms and gene deletions. In this chapter, we will try to get to grips with the terminology, what to do when faced with a child who is known to have a particular syndrome, when to suspect a syndrome that has not been diagnosed yet, and finally what the general otolaryngologist needs to know about some of the commoner syndromes in paediatric otolaryngology practice. Many of the syndromes will be covered in other chapters.

DEFINITIONS

A **syndrome** is a well-characterized constellation of major and minor anomalies that occur together in a predictable fashion, and for which a single underlying cause is known or suspected. The syndrome is a descriptive term for the collection of clinical features and often carries the name of the person who first described it (such as Down syndrome) or a description of the clinical features themselves (often as an acronym, such as CHARGE, or a simple list, such as velocardiofacial syndrome) while the **disease** is a way to describe the same entity in terms of its underlying cause (such as trisomy 21, which is the cause of Down syndrome, or 22q11 deletion, which is the cause of velocardiofacial syndrome).

A **sequence** occurs when a single developmental anomaly causes a chain of effects on nearby or related structures. For example, in the Pierre Robin sequence, the small mandible causes the tongue to fall back obstructing the pharynx (glossoptosis) and also to sit high in the oral cavity, preventing the palatal shelves from fusing, leading to a U-shaped cleft palate. These features are all directly related and can be considered as one. Thus, the Pierre Robin sequence may be found as one feature of Treacher Collins syndrome. Another example of a sequence would be an absent thymus leading to impaired T-cell immunity with recurrent ear infections (Di George sequence, which often occurs as a part of velocardiofacial syndrome).

In an **association**, a number of clinical anomalies appear together more often than would be expected by chance alone but no underlying genetic cause has been identified. An example would be the VACTERL association (vertebral defects, anal atresia, cardiac defects, tracheo-oesophageal fistula, renal anomalies and limb abnormalities). Once the genetic cause is known, the association becomes a syndrome. CHARGE is one such example, where what used to be known as CHARGE association is now more properly referred to as CHARGE syndrome since the cause has been identified as a mutation in the gene *CHD7*.[1]

GENERAL APPROACH TO THE CHILD WITH A SYNDROME

There are a few syndromes that occur commonly enough in otolaryngology practice that the otolaryngologist should probably know something about them. There are considerably more syndromes, many thousands in fact, that are so rare that the otolaryngologist may see them once in a lifetime. When faced with a syndrome you have never heard of, there is no shame in admitting the fact and no need to panic. Two minutes with any internet search engine will usually fill in most of the blanks. A more detailed literature search can be done at leisure for selected complex patients if required.

The best source of information, however, is usually the parents. For the rare syndromes they are usually the most experienced people in the room and you should not be afraid to use their expertise. In order to establish a good rapport with parents, it is not necessary to pretend to be the world's greatest expert in some rare syndrome that you looked up on the internet two minutes before; it is very important, though, to handle the family with sensitivity and respect. They will often be frequent hospital attenders who are under the care of many specialists and are therefore very 'medicalized'. They can be exquisitely sensitive to language so always remember that the child comes first and the syndrome second: you are dealing with 'a child who has Down syndrome', not 'a Down's kid', and certainly not 'a Down's'. Thankfully, old-fashioned terms like 'mongol' are long gone.

Parents can be very sensitive to any suggestion that their child is being treated less well than others because of their syndrome. A common cause of misunderstanding is in saying that a certain treatment 'is not worthwhile' because you think it is unlikely to work, which the parents hear as 'because the child is not worth treating'.

Ultimately, the syndrome is only ever of secondary importance. You are there to treat the child and to manage the same conditions that you always do. Whatever the syndrome, you are going to look at ear health and hearing, airway problems and recurrent infections, and you are going to be very careful with the cervical spine if the child is having an operation.

A child can present to the ENT clinic in one of two ways. Many children with enter the clinic with an underlying diagnosis of a syndrome already established, likely to be common in those with a characteristic phenotype. There are, however, a group of children who will present through ENT clinics with what would be considered common presentations and where there is a 'hidden syndrome'. In these cases the ENT surgeon is quite often an early opportunity to aid diagnosis. Naturally, this pathway can be more complicated and will also have to be handled incredibly sensitively.

Common presentations to ENT clinics include ear infections, hearing concerns and airway issues. These three presentations are often very common in children with syndromes as much as with the otherwise typically developing population of children. Coupled with an index of suspicion and additional features, this can be the path to early diagnosis.

SYSTEMATIC APPROACH TO THE CHILD WITH A SYNDROME

As some of the common ENT conditions can be associated with certain syndromes, this is a good basis upon which to assess and manage children with any syndrome. The approach can then be adapted to each specific syndrome and child.

Systematic management mainly involves assessment of otological manifestations and airway manifestations.

Otological manifestations

A history of recurrent acute otitis media (AOM) can be common in children with syndromes. Of course, ear infections are extremely common in all children. About half of all children have had an episode of AOM before their first birthday, increasing to 80% by their third birthday.[2] Most are managed in the community without seeing an otolaryngologist. In the UK, specialist referral is usually only requested for those with recurrent episodes of infection. During the consultation, the question inevitably arises as to whether the repeated infections are due to some underlying cause. Parents very often suspect some kind of systemic immune problem and for most the answer is 'no'. However, the otolaryngologist should be aware that among these many children with ear infections are a small number with specific syndromes that might not yet have been diagnosed.[2] In particular, a female child of short stature with a history of ear infections should make one alert to the possibility of Turner syndrome.

As well as infective problems, there are several types of hearing problem noted in children with syndromes. It is important to recognize these issues early and give consideration to the management options. Children with syndromes may have learning difficulties and additional support needs and addressing any hearing difficulties early on will help to reduce any potential handicap. Audiological screening can be a useful means of identifying problems and intervening early, although testing in this population can have its own challenges.

Conductive hearing loss can be common, particularly otitis media with effusion (OME). Although the management of this condition can mirror that in the typical childhood population, occasionally adjustments should be made for the underlying syndrome. For example, in children with Down syndrome, hearing aids are recommended in preference to ventilation tube insertion. However, in children with a cleft palate and a middle ear effusion, ventilation tube insertion is highly recommended. The high incidence of middle ear problems can lead to the development of cholesteatoma in these children and this should be kept in mind.

Sensorineural hearing loss should also be diagnosed early and treated appropriately. Hearing amplification options should be fully considered for each case, including standard hearing aids through to cochlear implantation. Children with craniofacial syndromes may present

some practical difficulties due to their head shape and/or behaviour, for example with respect to the wearing of hearing aids. Soft band and bone-anchored hearing aids may be more suitable options. In terms of cochlear implantation, again the anatomy may make surgery more tricky and there are naturally additional anaesthetic considerations to deal with for many of these children. Both these factors require surgery of this nature to be performed in specialist implant centres in tertiary level paediatric hospitals.

One should also remember to consider the cosmetic aspect under 'otology' management in terms of microtia. Again, these children should be managed in a multidisciplinary setting taking into account the hearing and cosmetic components. These settings should allow for an informed discussion on the merits of surgery in terms of auricular prostheses or auricular reconstruction.

Airway manifestations

Airway management in children with syndromes can be exceptionally challenging. Craniofacial abnormalities in particular can lead to great anxiety regarding airway management when the children present to other services for elective or 'routine' surgery: the anaesthetist may have to deal with a difficult intubation scenario in addition to a potentially more complicated peri-operative and post-operative period. Airway manifestations can also present as neonatal emergencies at birth, such as in bilateral choanal atresia or severe micrognathia.

In managing the airway, the level of obstruction should be considered with an awareness that this could be at the nasal level, nasopharynx, tongue base or at the level of the larynx/trachea/bronchi. Formal airway endoscopy (MLB) will allow for complete assessment of the level(s) of obstruction and exclude any other airway anomalies.

Adenotonsillar surgery can often be undertaken to help alleviate obstruction at the naso- and oropharyngeal level. The degree of adenotonsillar hypertrophy is not always clearly related to the degree of obstruction and no doubt the situation is much more complex with neurological and muscular tone often confounding the situation. Pre-operative assessment by means of sleep studies can be useful in assessing obstruction and certainly useful in guiding post-operative recovery.

Nasopharyngeal airways can be extremely useful airway adjuncts. Their use is indicated where the pathology relates to tongue-base collapse and micro/retrognathia as, for example, seen in Pierre Robin sequence (PRS). Often there can be symptomatic improvement as the child grows and a nasopharyngeal airway is a successful temporizing measure. However, in some situations formal surgery is required in the form of mandibular distraction or midface advancement.

Finally, tracheostomy may be required in some children with significant airway obstruction. The implications of a tracheostomy must be carefully considered for the child and the family. The procedure itself may also be more complex due to unusual airway anatomy, such as a tracheal sleeve.

WHEN TO SUSPECT THERE MAY BE A SYNDROME

Among the many children presenting on a daily basis to the otolaryngology clinic, there are a few whose symptoms are due to an underlying genetic condition. In most cases the underlying syndrome is obvious and has already been diagnosed, such as the child with Down syndrome. There are some syndromes, however, whose features may be subtler and easily missed. For some, the first presenting features may be in the ears, nose or throat and the otolaryngologist may be the first doctor to see the child and therefore the first to have the opportunity to spot the underlying diagnosis. This is an important opportunity to make potentially a huge difference to the child and family as making the correct diagnosis can affect not only the management of the otolaryngological condition but also of many other body systems.

The commonest clinical situation where this chance to make an early diagnosis occurs is in the child with recurrent AOM. It is very worthwhile looking out for a few underlying syndromes that might not have been diagnosed yet, specifically common variable immunodeficiency, Turner syndrome, mucopolysaccharoidosis and 22q11 deletion. The latter three have characteristic facies (which are often subtle) and mucopolysaccharoidosis and Turner also have short stature as a feature. All are discussed further below. Immunodeficiency is discussed in Chapter 7, Management of the immunodeficient child.

It is important that the ENT surgeon has knowledge of some of the less common genetic disorders in order that appropriate and timely referral for specialist management can be made.

SPECIFIC SYNDROMES

Down syndrome

Down syndrome is a common and easily recognizable disorder with familiar phenotype and genotype (trisomy of all or a critical portion of chromosome 21). This syndrome easily demonstrates the ear, nose and throat problems that can need to be considered in managing a child with any syndrome.[3]

The most common ENT reasons for referral in children with Down syndrome are OME, sleep-disordered breathing and laryngomalacia. The possibility of atlantoaxial subluxation in this group of children should mean that any surgical procedure involves very careful handling of the neck. Immunological aspects of the disease can lead to ventilator tube otorrhoea, persistent rhinorrhoea and recurrent upper respiratory tract infections. Endotracheal intubation can be difficult and often the child will need a smaller diameter ET tube than her age would suggest. There is an increased mortality in this group of children (×6 throughout infancy and ×17 until age 9 years) compared to age-matched controls.[4]

Otological aspects of the disease include the following:

- persistent otitis media with effusion – hearing aids should normally be offered to children with Down syndrome who have hearing loss due to OME[5]
- narrow and waxy ear canals – ventilator tube otorrhoea and early extrusion can be more common
- conductive hearing loss secondary to ossicular anomalies
- sensorineural hearing loss with increased labyrinthine dysplasia – inner ear dysplasia is common in children with Down syndrome
- increased incidence of cholesteatoma
- anatomical abnormalities of the facial nerve – tympanomastoid surgery can be especially challenging.

Hearing screening with behavioural testing throughout early childhood should be carried out to establish near-normal hearing with the use of amplification or ventilation tube insertion. Cholesteatoma should be suspected in continuously discharging ears.

Airway aspects of the disease include:

- obstructive sleep apnoea – relative adenotonsillar hypertrophy, upper airway obstruction as part of craniofacial condition including hypoplasia of pharynx and maxillary arch with nasal obstruction, sometimes generalized muscle hypotonia ('floppy baby')
- tracheobronchomalacia – increased incidence in this population and there may be a need for ventilation with/without tracheostomy and continuous positive airway pressure (CPAP)
- synchronous airway anomalies can be seen including a tracheal bronchus, subglottic stenosis and tracheo-esophageal fistula.

Annual screening for OSA until age 3–5 years is recommended. It is important to realize that, even after adenotonsillar surgery, there is a greater than 50% finding of residual OSA that will likely need medical intervention (e.g. CPAP). These children are unsuitable for day-case adenotonsillectomy and they will often require high-dependency care post-operatively.[6, 7]

Turner syndrome

Turner syndrome (TS) is characterized by the complete or partial loss of one X chromosome. TS is surprisingly common, affecting 1 in 2000 females, although perhaps only half have been formally diagnosed and are known to medical services. Some are diagnosed at birth due to characteristic features such as oedematous feet, while others are diagnosed in adolescence due to growth failure and delayed puberty. The vast majority of girls with TS present to otolaryngologists in their early years with recurrent AOM and OME, and for many this occurs long before the diagnosis of TS has been made.[8] Progressive mid-to-high tone sensorineural hearing loss is common in school years and early adulthood. Cholesteatoma is also not infrequent.[9] Early diagnosis can make a huge difference to these patients as it enables the detection of heart anomalies, which are commonly present, as well as growth hormone treatment for short stature. Suspicion is key: consider TS in any girl with ear problems and short stature, and refer on to an endocrinologist if concerned. If she is the shortest girl in her school class, think, 'could this be Turner syndrome?'

22q11 deletion syndrome

22q11 deletion syndrome encompasses the clinical conditions previously termed velocardiofacial syndrome and Di George syndrome which are now known to be different manifestations of the same genetic defect. A variety of clinical features can occur but not in every child.[10] Common features include submucous cleft palate, congenital heart anomalies, absent thymus with impairment of T-cell immunity (Di George sequence) and characteristic facial features. The ENT clinical features result from abnormal development of structures derived from the third and fourth pharyngeal pouches. The first presentation to medical services may well be with recurrent episodes of AOM due to the impaired T-cell immunity. Another presentation to the otolaryngologist is with a congenital glottic web which is almost always diagnostic of 22q11 deletion (see Chapter 30, Congenital disorders of the larynx, trachea and bronchi).[11, 12] Again, the phenotypic profile is highly variable and awareness and suspicion are key. If there is suspicion of 22q11, full ENT assessment including laryngoscopy should be performed and referral to a geneticist and cardiologist initiated.[13]

Mucopolysaccharoidoses

The mucopolysaccharoidoses (MPS) comprise a group of conditions that result from the deficiency of lysosomal enzymes causing the accumulation of glycosaminoglycans in tissues. Head and neck structures are frequently involved early and the otolaryngologist may see children before the onset of systemic disease.[14] Features commonly include recurrent otitis media, mixed hearing loss, upper airway obstruction +/– obstructive sleep apnoea and coarse facial features. Due to the non-specific clinical features, diagnosis is frequently delayed but early diagnosis is essential, particularly in Hunter syndrome, where enzyme replacement therapy is now available.[15] MPS is also associated with intubation difficulties and may pose a significant anaesthetic risk. OSA is extremely common, with a prevalence of up to 90%, and patients may benefit from adenotonsillectomy.[16] Suspicion of MPS should prompt specialist referral, and confirmation is with urinary glycosaminoglycan measurement and enzyme assays.[14]

CHARGE syndrome

CHARGE syndrome is an autosomal dominant genetic disorder typically caused by mutations in the chromodomain helicase DNA-binding protein-7 (*CHD7*) gene.[1, 17, 18] The acronym 'CHARGE' denotes the non-random

association of coloboma, heart anomalies, choanal atresia, retardation of growth and development, and genital and ear anomalies, which are frequently present in various combinations and to varying degrees in individuals with CHARGE syndrome.[19]

Neonatal presentation:

- small for gestational age
- dysmorphic features
- respiratory distress/cyanosis
- swallowing/feeding difficulty
- failed newborn hearing screen
- inability to pass nasogastric tube.

Choanal atresia is membranous or bony, and bilateral in over 50% of cases, usually presenting in the newborn period with a cyclical pattern of respiratory distress. This can be a threat to life because infants cannot establish mouth breathing. Of all features of CHARGE syndrome, choanal atresia (when bilateral) is the most easily ascertained and requires early surgical correction. When associated with other anomalies (e.g. cyanotic heart disease, tracheoesophageal fistula and/or atresia), prognosis is poor. Unilateral atresia may present as persistent nasal discharge in early childhood.

External ear malformations are seen in 90–100% of patients. Ears may be small, simple, low-set, and/or cup-shaped; a protruding helix may be unravelled.

Vestibular or cochlear defect leads to sensorineural deafness. Middle ear problems cause conductive hearing loss and are commonly due to ossicular malformations, stapedius tendon abnormality, or serous effusion. CT scan of the temporal bone demonstrates partial or complete semicircular canal hypoplasia.

Syndromes discussed elsewhere

Syndromic craniosynostosis (Pfeiffer, Apert, Crouzon and Saethre–Chotzen syndromes) are discussed in Chapter 19, Craniofacial surgery.

Syndromes causing deafness (such as Pendred, Waardenburg and Usher, as well as many others) are discussed in Chapter 10, Management of the hearing impaired child.

KEY POINTS

- Far too many syndromes have been described for anyone to be familiar with them all, but a few common ones should be well-known to any paediatric otolaryngologist.
- Be careful with the words you use in front of parents as they are often very sensitive to anything that sounds like a lack of respect for the child.
- Regardless of the nature of the syndrome, the role of the otolaryngologist will most often be to address issues of hearing, recurrent infections and airway obstruction, whilst always being careful with the cervical spine.
- Some children presenting with common otolaryngological problems may have an underlying syndrome that has not yet been diagnosed. Be alert to any features that may allow you to make the diagnosis.

CHAPTER 7

MANAGEMENT OF THE IMMUNODEFICIENT CHILD

Fiona Shackley

SEARCH STRATEGY

Data in this chapter may be updated by a Medline search using the keywords: immunodeficiency, otitis media, sinusitis, mastoiditis, otolaryngological disease, ENT, nasopharyngeal colonization, hypogammaglobulinaemia and HIV.

INTRODUCTION

The infant nasopharynx becomes colonized with microorganisms from shortly after birth.[1] There is a consequent constant balance of host, microbial and environmental factors that allow individuals to be colonized with potentially infectious organisms or allow microorganisms to breach host defence to cause local or systemic disease.[2] In the young child with an immature immune system, recurrent respiratory tract infection, particularly otitis media, is common. Studies carried out prior to the widespread introduction of pneumococcal conjugate vaccines indicate that 83% of children will have suffered one episode of otitis media by 3 years of age and 46% will have had at least three episodes.[3] Recurrent infections of the upper respiratory tract are also common in children with primary immunodeficiency (PID). ENT specialists may be the first clinicians to see a child with an immune defect and have a key role in identifying these children. This is also the case for children with HIV infection who may present to an ENT specialist before their diagnosis has been confirmed. Early diagnosis and commencement of treatment for both primary and acquired immune deficiency improves long-term outcome.[4, 5] Unfortunately, identifying the children who need further investigation can be difficult, although other features including failure to thrive, absence of or excessive lymphadenopathy, dysmorphic features and skin problems should raise concerns.[6] Some children with minor immune defects may only become symptomatic because of other associated features including allergic tendency, GOR and Eustachian tube dysfunction.[7, 8]

PRIMARY IMMUNODEFICIENCY

Children born with a reduced immune system, or the tendency to develop a reduced immune system over time, are classified as having PID.[9] Ascertainment of the true incidence of these conditions is difficult. An estimate from a US telephone survey indicated a prevalence of PID in the US of 1:2000.[10] Over 60% of these immune problems relate to antibody production.[10, 11] Antibody plays an essential role in the process of opsinophagocytosis,[12] destroying common organisms in ear and sinus disease including *Streptococcus pneumoniae*, non-typable *Haemophilus influenzae* and *Moraxella catarrhalis*. These are clearly children or adults who may have seen an otolaryngologist before the diagnosis is considered.

Identifying children with immune deficiency

Several guidelines are available to help clinicians identify children with immune deficiency. The Jeffrey Modell '10 warning signs of infection'[13] indicate that immunodeficiency should be considered in any child with more than four new ear infections in one year; more than two episodes of severe sinusitis pneumonia, infections that do

not respond to routine antibiotics, failure to thrive or a family history of immunodeficiency. Consequent studies using these risk indicators have shown that, particularly for antibody deficiency, it can be very difficult to differentiate the immunologically normal and abnormal child in the absence of features such as poor growth or family history.[14] The current ESID guidelines, while not giving a threshold for ENT infections that might indicate the need to investigate, do give clear pathways for appropriate investigations.[6]

Transient hypogammaglobulinaemia of infancy

All children rely on transplacental transfer of maternal antibodies during the last trimester of pregnancy, which helps protect them over the first 6 months of life while the infant's antibody production becomes adequate.

In some children, there appears to be a delay in this maturational process resulting in low IgG, which can be associated with a reduced IgA and IgM. Transient hypogammaglobulinaemia of infancy (THI) is a diagnosis of exclusion and a definitive diagnosis is only possible over time when the problem resolves. In paediatric series this is the commonest form of symptomatic antibody deficiency.[15, 16] The pathogenic process behind THI is not understood. A small number of children continue to have problems with infections and persist in having low antibody levels or fail to make adequate response to their routine immunizations. The majority are reported to improve by the age of 4 years although in some children the IgG remains low into late childhood.[16, 17]

Hypogammaglobulinaemia is common in preterm infants who may not be symptomatic although routine prophylactic immunoglobulin is not recommended.[18] Also, high levels of cord blood pneumococcal-specific antibodies did not seem to provide sufficient protection for Aboriginal infants who are known to be at increased risk of early otitis media illustrating the fact that low antibody levels alone may not be the sole explanation for recurrent ENT infections in early infancy.[19]

If low immunoglobulin levels are identified, it is important to be sure that there is not a more significant underlying immune defect present.[6]

IgA deficiency/ IgG subclass deficiency and specific antibody deficiency

IgA deficiency is present in around 1 in 600 blood donors.[20] Most individuals with IgA deficiency are completely well and, in many children, the deficiency is transient. Some people do suffer more frequent infections including ear and sinus disease and occasionally develop progressive antibody deficiency.[21] This is more likely if they have an associated IgG subclass deficiency, particularly IgG2, or specific antibody deficiency (SAD). Activity against pneumococcal capsular polysaccharide appears best mediated by the IgG2 subclass which young children may be poor at generating. IgG2 deficiency is commoner in some series of children with recurrent otitis media.[22] However, asymptomatic IgG2 deficiency is also well documented.[23] Quality of antibody production can be assessed by looking at protective levels of antibody following immunizations. A group of individuals has been described who have reduced ability to make antibodies to polysaccharides, a key component of the capsular wall in some organisms. Poor polysaccharide responses are normal in children under 2 years but are also seen in some older children and adults where it will be labelled as SAD. While definitions of this condition are available,[24–26] the introduction of routine pneumococcal conjugate vaccine immunizations and lack of access to standardized assays to assess response adds controversy to diagnosis of this condition.[27, 28]

Common variable immune deficiency

In combined adult and paediatric data common variable immune deficiency (CVID) is the commonest symptomatic antibody deficiency[29] defined by a reduced IgG (beyond the age of 4 years), a history of infections and often inadequate response to immunizations.[9] A proportion of children with CVID may initially have been labelled as THI but continue to be symptomatic and have low IgG levels in later chidlhood. In a recent paediatric series, 88% of children with CVID had recurrent respiratory tract infections, 78% otitis media and 78% sinusitis.[30] Around 10% of individuals with CVID[31] have an identifiable gene defect but the cause for the majority of CVID remains unclear. There are two peaks of onset, in mid-childhood and early adulthood. Delay from symptoms to diagnosis and treatment is usually around 4–5 years.[30, 32] These are clearly the type of children who may have seen an otolanyngologist before the diagnosis is considered.

X-linked agammaglobulinaemia

A small group of children, predominantly boys, who present with severe infection and a paucity of lymphoid tissue will have X-linked agammaglobulinaemia. Due to defects in the *BTK* gene, affected boys fail to manufacture mature B-cells and consequently make no or very little IgG. While some of these children suffer serious life-threatening infections, recurrent otitis is the commonest infection identified prior to diagnosis.[33] In a small number of patients, deletions in the terminal portion of the *BTK* gene may extend to involve the deafness dystonia protein gene resulting in sensorineural deafness.[34] These children are differentiated from THI and CVID patients initially on the basis of extremely low IgG, IgA and IgM or absent B-cell numbers. Consequent protein and molecular studies confirm a *BTK* defect in most children. In a small number of individuals there are autosomal recessive conditions that result in a similar phenotypes affecting both boys and girls.[35] Boys with X-linked agammaglobulinaemia usually present at 6–18 months of age but diagnosis may be delayed till

later in childhood in 10–15%, unfortunately sometimes after children have already sustained lung and ear damage. Bruton's use of regular immunoglobulin infusions was the start of what is a key treatment for children with antibody deficiency.[36]

Other conditions that may mimic antibody deficiency

X-linked hyper IgM syndrome may present like CVID with absent or low IgG and IgA but normal or elevated IgM.[37] The defect in CD40 ligand results in T- and B-cell functional problems. Hyper IgE syndrome[38] and DOK 8 deficiency[39] are both associated with eczematous skin problems, raised IgE and recurrent infections, again particularly otitis media. Wiscott–Aldrich syndrome, due to mutations in the WASP cytoskeletal protein, also often presents with severe eczema, thrombocytopaenia and ear infections.[40] These children are at increased risk of opportunistic infection and may require bone marrow transplant in addition to immunoglobulin replacement.

TREATMENT OF ANTIBODY DEFICIENCY

Children with antibody deficiency, THI and SAD with mild infections may be managed with prophylactic antibiotics including amoxicillin, azithromycin and cotrimoxazole.[41, 42] There is very little trial evidence to support this but practice has been based on studies from otitis media.[43] For more severe immunodeficiency, and certainly X-linked agammaglobulinaemia, or in children where antibiotic prophylaxis alone does not control infections, immunoglobulin replacement can be given either as an intravenous infusions 0.4–0.6 g/kg every 3–4 weeks or a weekly subcutaneous infusion which can be easily given at home and is well tolerated by children. There is good evidence that adequate immunoglobulin replacement improves long-term outcome.[44, 45]

Phagocyte abnormalities

Due to the key role of neutrophils in phagocytosis, ENT infections are also frequently seen in children with reduced neutrophil numbers and function. In infancy, neutropaenia may be consequent to a number of known molecular defects but is also seen in conjunction with some metabolic conditions including glycogen storage disease. These children can be at risk of life-threatening sepsis but otitis media, oral ulceration and abscesses are also common.[46, 47] The commonest cause of neutropaenia in our practice in young children is benign autoimmune neutropaenia or alloimmune neutropaenia. Recurrent otitis media can be a frequent problem in these children and severe mastoiditis or adenitis may be a presenting feature.[48] A blood count will identify children with persistent neutropaenia who can then have consequent genetic or autoimmune studies to define the cause. Congenital neutropaenia usually requires treatment with granulocyte-colony stimulating factor (G-CSF) to increase neutrophil numbers but may require bone marrow transplant. Autoimmune neutropaenias can often be managed with antibiotic prophylaxis and prompt treatment of infections.[47]

Defects in the neutrophil oxidative burst pathway are well described, resulting in chronic granulomatous disease. These children can develop deep-seated infections, sometimes with unusual organisms including *Serratia species, Burgholdheria cepacia* and fungal infections.[49] These may cause severe adenitis, mastoiditis or sinusitis.[50] This should always be considered in children with particularly severe disease who may present to ENT teams for acute surgical intervention. Unlike with many other immune defects, these children may not have problems early in infancy and can present in late childhood with an unusual infection. Management is with long-term prophylactic antibiotics and antifungals and, with an appropriate donor, bone marrow transplant has been very successful. Most cases are X-linked but AR forms also occur.

Children with defects in leucocyte adhesion molecules may also present in infancy with severe otitis and mastoiditis.[51] One of the key laboratory findings that may alert an ENT surgeon to this defect is the presence of a very high WBC. Consequent questioning may reveal a history of delayed cord separation.

Other innate immune system defects

Deficiencies in the compliment system are more likely to present with septicaemia than recurrent ear or sinus infections.[52] However, deficiency in mannose-binding lectin (MBL), which facilitates complement activation, is relatively common in the population[53] and may, particularly in conjunction with other immune system abnormalities or Eustachian tube dysfunction, contribute to recurrent ear and sinusitis infections.[54, 55] No specific treatment options are available apart from prompt antibiotic treatment.

IMMUNE DEFICIENCY IN OTHER PAEDIATRIC SYNDROMES

Di George or velocardiofacial syndrome,[56] CHARGE (coloboma, heart defects, atresia choanae, retardation of growth, genital anomalies and ear abnormalities)[57] and Down syndrome[58] are all linked to an increased risk of ear infections through facial structure and palatal abnormalities but are also at risk of immune deficiency which, in the case of 22q deletions, may be quite severe. Clinicians should have a lower threshold for considering immune deficiency in children with dysmorphic syndromes. Children with developmental delay and associated microcephaly may have a defect in DNA repair or chromosome stability. Immune deficiency is a recognized complication of many

of these conditions,[59] the most notable being ataxia telangiectasia where recurrent otitis media is a well-recognized common complication.[60]

Autoimmune lymphoproliferative syndrome

Autoimmune lymphoproliferative syndrome (ALPS) is an uncommon group of conditions associated with defects in the apoptosis pathway. The degree of immune deficiency associated with this condition is variable but children can present in infancy and early childhood with persistent, sometimes, massive cervical adenopathy.[61]

MHC Class 1 deficiency

Rarely older children may present with sinusitis, nasal polyposis and bronchiectasis due to MHC Class 1 deficiency.[62]

Severe combined immune deficiency

Children with these severe immune defects will not usually present to the ENT team at diagnosis, as the majority will suffer severe generalized infections in early life.

INVESTIGATIONS FOR PID

The European Society for Immunodeficiencies (ESID) guidelines provide a helpful pathway indicating initial screening test for children with recurrent ENT infections should include FBC, and measurements of IgG, IgA and IgM.[6, 9] Perisistent or recurrent neutropaenia may indicate a congenital or autoimmune neutropaenia requiring further genetic and autoantibody testing. If low immunoglobulins are identified, lymphocyte subsets should be carried out particularly to ensure the child has adequate B-cell numbers. Responses to routine immunizations should also be evaluated including Hib, tetanus and *Pneumococcus*. For children who have had pneumococcal conjugate vaccine, measurement of pneumococcal serotypes if available should be carried out rather than total pneumococcal antibodies. Children with low vaccine responses should be offered booster immunizations and the response reassessed in 4–6 weeks. Looking at children's response to Pneumovax is recommended by some guidelines but lack of access to standardized tests to assess the response can limit the clinical utility of this. If symptoms are persistent, IgG subclasses, MBL and complement studies CH50 APCH50 are recommended. Children with other features to suggest a more fundamental immune defect including failure to thrive, family history, severe eczema, abnormal lymphadenopathy or dysmorphic features should be discussed with the local immunology service as further investigation is likely to be indicated. In the context of features suggesting SCID, including lymphopaenia, the local paediatric team should be urgently alerted.

IMPACT AND USE OF IMMUNIZATIONS

The introduction of routine infant immunization with pneumococcal conjugate vaccines in many developed countries since 2000 has had a significant impact on invasive pneumococcal disease[63] but has also reduced otitis media[64] and the need for surgical intervention with tympanostomy tubes.[65] There is evidence that pneumococcal strains present in the older pneumococcal polysaccharide vaccine (PPV) but not current conjugate vaccines are now causing more otitis media[66] but there is no evidence unfortunately that giving additional doses of either conjugate or PPV to children with recurrent otitis media reduces infections.[67, 68] There is also some concern that repeated doses of PPV may result in blunting of the immune response.[28]

HIV/ACQUIRED IMMUNE DEFICIENCY

HIV is estimated to affect 3.4 million children worldwide.[69] Rates of new infections in children have dramatically reduced worldwide through treatment interventions that prevent mother-to-child transmission. The majority of children with HIV acquire infection from their mothers before birth, during delivery or during breastfeeding. Without control of maternal infections with highly active antiretroviral therapy (HAART), and infant prophylaxis, mother-to-child transmission was around 25%.[70] With appropriate maternal and infant medication, advice against breastfeeding or control of maternal virus while breastfeeding and, where indicated, Caesarean section, it is anticipated that transmission can be reduced to less than 2% worldwide and is already less than 1% in some developed countries.[71]

ENT complications

Many children become symptomatic over the first 2 years of life but others may be well into late adolescence.[72] In this group of children parotid enlargement may be a common feature and may be the initial presentation to ENT services. Otitis media and chronic suppurative complications are common, with a trend to increasing ear infections over time as the child's immune system fails.[73]

Conductive hearing loss as a consequence of ear infections can have significant impact on a child's well-being and development. In addition, HIV-infected children appear to be at increased risk of sensorineural deafness, tinnitus and vestibular symptoms, highlighting the importance of audiological assessment in all HIV-infected children.[74] Access to HAART has had a significant impact on children's survival and may have led to a decrease in the number of children with ENT manifestations of HIV.[75, 76] HIV-infected children will still, however, suffer from ENT-related problems and potentially require surgical intervention including tympanostomy tubes

and myringoplasty. Infectious cervical lymphadenitis with common and opportunistic organisms including tuberculosis and atypical mycobacteria may also present neck swelling to ENT specialists.

Who and how to test

UK national guidelines for HIV testing list recurrent and troublesome ear infections and chronic parotitis as clinical indicators for HIV testing in children.[77] While routine testing of all children with recurrent ear infections may not be indicated, HIV testing in children with chronic parotitis is recommended irrespective of there being no other apparent risk factors. HIV should also be considered if a child is found to have significantly raised immunoglobulins when being investigated for a PID.[6] Unexplained lymphadenopathy is an indication in adult but not paediatric UK guidance but is a well-described feature, though the clinical appearance may be difficult to differentiate in infected and uninfected children.[78]

Any trained heath professional should be able to obtain consent for HIV testing.[77] However, HIV testing a child adds the additional complexity of the implications the test result may have for the family, particularly if the parents themselves are unaware of their own underlying diagnosis. Usually local paediatric or infectious disease colleagues are happy to be involved. The significant stigma, guilt and concern around disclosure can make it extremely difficult for parents to agree to testing. Parental refusal to have HIV testing may then become a child protection issue requiring involvement from social care and the court system.[79] Wherever possible, however, healthcare staff should work with families to encourage them to have testing carried out and engage with ongoing clinical input voluntarily.

Initial screening for children over 18 months of age is by HIV serology and p24Ag, which should then be repeated and include a DNA PCR and RNA viral load. Children under 18 months of age require testing using DNA or RNA PCR.[80] A CD4 count may be arranged with the confirmatory testing but CD4 count alone should not be used as a surrogate for HIV testing in families who will not consent to testing.

TABLE 7.1 ENT features and staging (adapted from PENTA)[80]

Clinical stage WHO or CDC	ENT features in children
Mildly symptomatic WHO 1 and 2; CDC A	Recurrent otitis media +/– chronic otorrhoea Recurrent sinusitis Chronic parotitis
Moderate to severe symptoms WHO 3 and 4; CDC B and C	Oral candidiasis Oesophageal candidiasis Extrapulmonary TB Atypical mycobacterial disease Necrotizing gingivitis Recurrent oral HSV Oral hairy leukoplakia Lymphoma/Kaposi sarcoma

When to treat

A variety of guidelines is available to indicate when it is appropriate to commence children on antiretroviral treatment based on a combination of symptoms and CD4 count. A number of common ENT presentations are seen in the relatively well HIV-infected child who may not yet need to be on medication unless associated with a low CD4 count. Other conditions that may present to ENT are key indicators themselves of the need to start treatment (**Tables 7.1** and **7.2**).

Families need significant support with compliance with HAART. Most children show rapid improvement in their CD4 count and immune reconstitution over the first few months of treatment. However, for some children the residual damage caused by recurrent ear and chest infections may mean they continue to have problems that need ongoing input from the ENT team.

TABLE 7.2 Age-specific thresholds to start treatment (adapted from PENTA)[80]

	Under 12 months	1–3 years	3–5 years	Over 5 years
Clinical stage	Start all	CDC B or C WHO 3 and 4	CDC B or C WHO 3 and 4	CDC B or C WHO 3 and 4
CD4 count	Start all	CD4 < 1000 (25%)	CD4 < 500 (20%)	CD4 < 350

KEY POINTS

- Children with primary or acquired immunodeficiency will commonly present with ENT problems.
- Clinical features may not differentiate immune-deficient children from normal children.
- Simple baseline investigation can screen out a number of severe immune defects.
- Close working between ENT teams and the local paediatric immunology/infectious disease services should be encouraged.

CHAPTER 8

HEARING SCREENING AND SURVEILLANCE

Sally A. Wood

SEARCH STRATEGY

Data in this chapter may be updated by a Medline search for relevant articles published in English, using the following keywords: infant or newborn and hearing screening and hearing impairment.

INTRODUCTION

Any discussion of screening must be grounded in an understanding of the principles of screening as a public health exercise and an understanding of the epidemiology of the condition of interest, in this case moderate–profound permanent childhood hearing impairment (PCHI). This chapter starts with an outline of the key definitions and principles of screening, before proceeding to review evidence on the epidemiology of permanent childhood hearing impairment. The case for newborn screening and the current performance of the newborn hearing screening programme in England is summarized. The need for surveillance in the preschool years is reviewed and the school entry screen is briefly discussed.

PRINCIPLES AND DEFINITIONS

Screening

Screening is a public health service in which members of a defined population who do not necessarily perceive they are at risk of or already affected by a disease or complications are asked a question or offered a test, to identify those individuals who are more likely to be helped than harmed by further tests or treatments to reduce the risk of a disease or its complications.[1] In the UK the National Screening Committee (NSC) assesses the evidence for the introduction of national screening programmes and monitors the effectiveness and quality of these programmes in the English NHS.

Screening is ethically different from clinical practice; in screening the individual has not presented with a symptom or concern but is offered a test. When you treat an ill person, they have the possibility of benefit as well as the risk of harm. In screening some people who do not have the condition may experience the harm but have no benefit. Screening is not an infallible process and in all screening programmes there are inevitably individuals who fail the screen but do not have the condition (**false positives**), and individuals who pass the screen but do have the condition (**false negatives**). Thus there is an added ethical imperative to ensure that the screening programme does more good than harm.[2] The most likely potential harms from newborn hearing screening are related to parental anxiety for the parents of babies who fail the screen but do not have an impairment (false positives) and the ability of audiology services to make a correct and timely assessment in screen positives.

The principles that a screening programme should satisfy have been identified by Wilson and Junger[3] (1–10 below) and expanded by Haggard and Hughes[4] (11–14) in their review of screening for hearing impairment in children.

1. The condition (hearing impairment) should be an important health problem.

2. There should be an accepted treatment, i.e. an acceptable means of habilitation for those identified by the screen.
3. Facilities for assessment, diagnosis and treatment should be available.
4. The hearing impairment should be recognizable at an early stage.
5. There should be a suitable test for use as the screen.
6. The test should be acceptable to the parents and to the child.
7. The natural history of the condition should be known and understood.
8. There should be an agreed policy on who to treat.
9. The cost of case finding (including all consequential costs of the screening programme) should not be disproportionate to overall healthcare costs of care for the hearing-impaired child.
10. Case finding should be seen as a continuing process.
11. The incidental harm should be small compared to the overall benefits.
12. There should be guidelines on how to explain results to parents with appropriate support.
13. All hearing screening arrangements should be reviewed in the light of changes in demography, epidemiology and other factors.
14. Cost and effectiveness of hearing screening should be examined on a case-type basis to maximize the effectiveness and benefit for each type before considering overall costs, effectiveness and benefits.

There are a number of key definitions relevant to screening programmes which should be used in the quality assurance and audit of any screening programme. These measures are defined in Table 8.1 and described below.

Coverage is the proportion of the eligible population who complete the screen.

Screen positive/fail (A+B) is a screening result that is greater than or equal to a specified cut-off level. True positives (A) are those who fail the screen and have the condition. False positives (B) are those who fail the screen and do not have the condition.

Screen negative/pass (C+D) is a screening result that is less than the specified cut-off level. True negatives (D) are those who pass the screen and do not have the condition. False negatives (C) are those who pass the screen and have the condition. Screening programmes attempt to reduce false negatives to a minimum, while keeping false positives within manageable service levels. The aim of a screen is to refer on a manageable proportion of the population for further (diagnostic) tests, that proportion being likely to contain as many of the true cases in the population as possible.

Sensitivity (A/(A+C)) is the proportion of individuals with the target condition in the population who are correctly identified by the screen. The term can be applied to a screening test, or to the screen as a whole (if, as is the case with newborn hearing screening, the screen consists of more than one test) or to the screening programme as a whole. **Programme sensitivity** is the proportion of the subjects in the whole population with the specified condition (impairment) who are detected by the screening programme. It is a function of the screen sensitivity and the coverage achieved by the screen programme.

Specificity (D/(B+D)) is the proportion of individuals without the target condition in the population who are correctly identified as such by the screen. As with sensitivity, the term specificity may be applied at the level of test, the screen or the programme. **Programme specificity** is a function of specificity and coverage.

Positive predictive value (PPV) (A/(A+B)) is the proportion of individuals with a positive test result who have the target condition.

Yield is the number of cases identified by a screen. The yield is sometimes expressed as the number of cases identified via the screen per 1000 individuals screened, thus allowing comparison with published prevalence figures, and acting as a surrogate for sensitivity (since sensitivity can only be established in retrospect, once all false negative and missed cases have been found). The yield of a screen is affected by coverage and sensitivity, and affects the cost per case identified. The **incremental yield** is the number of true cases referred by a screen when any true cases that would have been or were identified by preceding screening, surveillance programmes or responsive services are excluded.

Incidence is the number of new instances of the condition (impairment) occurring during a certain period (e.g. a year) in a specified population. Thus, in an average-sized health community with 5000 births per year, an incidence of between five and ten cases of congenital permanent childhood hearing impairment of moderate or greater degree might be expected.

Prevalence is the total number of individuals who have a given disease or condition (impairment) at a given point in time per population figure (e.g. per 1000 live births). Davis et al.[5] have suggested a figure of 1.12 per 1000 for congenital permanent bilateral hearing impairment of moderate or greater degree.

Haggard and Hughes extended the screening criteria to include costs and cost-effectiveness as

TABLE 8.1 Measurement of screen performance

Screen outcome	Condition present	Condition absent	Total
Fail (positive)	A: true positive	B: false positive	A+B
Pass (negative)	C: false negative	D: true negative	C+D
Total	A+C	B+D	A+B+C+D

important issues for screening programmes (points 9 and 14 above). **Cost-effectiveness** analysis measures costs per unit of health gain.

Lost to follow-up is a measure of the percentage of screen positives that fail to enter follow-up. This is usually measured at a specific point in time.

Surveillance

The concept and practice of child health surveillance has been extensively discussed in the literature.[6,7] It is generally recognized to include a partnership between parents, children and health professionals in which parents are empowered to make use of services and expertise according to their needs. Ongoing surveillance for childhood hearing impairment is of considerable importance:

- Newborn hearing screens will not find all those with permanent hearing loss, because of late onset and progressive hearing loss.
- Any screening programme will miss some true cases.
- Mild permanent hearing loss will not be identified by the screen.
- Surveillance is a more justifiable approach to identification of children with persistent otitis media with effusion (OME) than a screening programme.

EPIDEMIOLOGY: PREVALENCE AND RISK FACTORS

Terminology and definitions

In the sections that follow, hearing impairment is categorized as mild, moderate, severe or profound on the basis of hearing threshold in dB HL (hearing level) averaged over the frequencies 0.5, 1.0, 2.0 and 4.0 kHz for the better hearing ear as follows:

- Mild 21–39 dB
- Moderate 40–69 dB
- Severe 70–95 dB
- Profound >95 dB.

This categorization is widely used in the literature.[5] It is slightly different from that adopted by the British Society of Audiology.[8] The World Health Organization has recently defined an alternative classification.[9]

Permanent childhood hearing impairment (PCHI) includes hearing impairment that results from a structural abnormality in the outer ear, middle ear as well as sensorineural hearing loss. The term congenital is used to denote hearing impairment that is present at, or very soon after, birth. While this is not a strictly accurate use of the term, it has been commonly used as a functional definition. Acquired hearing impairments are considered to be (i) postnatally acquired PCHI (e.g. as a sequela of meningitis or head injury); (ii) progressive hearing impairments usually diagnosed following ongoing progression of the impairment post diagnosis; (iii) impairments that are considered to be late-onset, with no evidence of progression but with some evidence of previously normal hearing.

Congenital permanent bilateral hearing impairment

The quality of published studies on the prevalence of PCHI is variable, with many studies marred by lack of clarity on case definition, uncertain methodology and incomplete case ascertainment. Of the better studies, those of Fortnum and Davis[10] and Fortnum et al.[11] are probably the most extensive and reliable. Fortnum and Davis report the results of a retrospective ascertainment of all cases of permanent bilateral hearing loss of moderate or greater degree in children born in the UK's Trent health region between 1985 and 1993. Based on the birth cohorts for 1985–1990, the prevalence of moderate to profound congenital permanent bilateral hearing impairment was 1.12 (95% CI 1.01–1.23) per 1000 live births as shown in Table 8.2. Acquired impairment was estimated at 0.21 per 1000. Prevalence is presented per 100 000 for ease of interpretation.

In a later study Fortnum and colleagues[11] reported prevalence rises from 0.91 per 1000 (95% CI 0.85–0.98) for the 3-year-old cohort to 1.65 per 1000 (95% CI 1.62–1.68) for the 9-year-old cohort, where it levelled off. The authors conclude that there are more late-onset and progressive permanent childhood hearing impairments than previously suspected. However, this prevalence was arrived at by including an adjustment for under-reporting based on data for the relatively small subgroup that had received cochlear implants. To date there are no longitudinal population studies that confirm this rise in prevalence. More recently Watkin and Baldwin[12] have shown a prevalence of 1.51 (95% CI 1.11–1.92)/1000 at the end of the first year in primary school (i.e. at age 6 years). Some of the children in their study had moved from countries outside the UK without newborn hearing screening and four had acquired a PCHI following meningitis. For Australian children Ching et al.[13] reported a similar prevalence of 1.57/1000 at age 16 years.

Irrespective of the true increase in prevalence over childhood these data support the use of newborn hearing

TABLE 8.2 Prevalence of PCHI[10]

	Severity (dB HL)	Prevalence per 100 000	95% CI
Congenital	40–69 (moderate)	64	56–73
	70–94 (severe)	23	19–29
	≥95 (profound)	24	20–30
Acquired	40–69 (moderate)	9	7–12
	70–94 (severe)	5	3–8
	≥95 (profound)	7	5–10

screening for the identification of the 1.12 (or thereabouts) congenital cases per 1000 births.

Risk factors

Risk factors for permanent congenital hearing loss are well established (Joint Committee on Infant Hearing, JCIH).[14] Davis and Wood[15] showed that babies admitted to a neonatal intensive care unit for more than 48 hours were 10.2 (95% CI 4.4–23.7) times more likely to have a permanent hearing loss (greater than 50 dBHL in this study) than those who did not undergo intensive care. Fortnum and Davis[10] showed that prevalence was increased 14-fold for children with a family history of early permanent childhood deafness. Babies with craniofacial anomalies associated with hearing impairment (e.g. cleft palate) are also at high risk for hearing loss. The large-scale Wessex study[16] reported that, of 25 000 newborns screened, 8.1% fulfilled high-risk criteria. The three major risk factors are:

- history of treatment in a neonatal intensive care unit (NICU) or special care baby unit (SCBU) for more than 48 hours
- family history of early childhood deafness
- craniofacial anomaly (e.g. cleft palate) associated with hearing impairment.

About 60% of congenital bilateral permanent hearing impairment of moderate degree or greater is associated with one or more of these three risk factors, in the proportions 29.3% NICU, 26.7% family history and 3.9% craniofacial anomaly.

Acquired and late-onset permanent bilateral hearing impairment

Acquired hearing impairment is one which, on the basis of case history, was not considered to be present and detectable using appropriate tests at or very soon after birth. Meningitis is the most common causes of acquired hearing impairment in children.[5] There remains a lack of evidence about the prevalence of progressive or late-onset impairments. Any newborn hearing screening programme will, of course, not identify these cases; other means of finding them are required.

Unilateral permanent hearing loss

Previous studies have suggested a prevalence of around 1 per 1000 in school-age children for unilateral impairment although prior to newborn hearing screening it was difficult to estimate how much of this was congenital. In the Newborn Hearing Screening Programme (NHSP) in England all babies that are screen positive, whether unilaterally or bilaterally, are referred for immediate follow-up. The rationale for this is to increase the sensitivity for bilateral PCHI rather than to identify unilateral PCHI per se. However, this has provided data on the prevalence of unilateral PCHI at 0.61 per 1000 screened.[17, 18] Such early identification does lead to issues about optimal management of unilateral PCHI.[19]

Mild hearing loss

Prevalence of mild hearing loss has been difficult to ascertain. Estimates based on clinical populations are biased as those with difficulties arising from a mild loss present to clinical services whereas those not experiencing difficulty do not. Hence population data are needed to estimate prevalence. Hall et al.[20] assessed hearing in children at age 7, 9 and 11 years as part of the ALSPAC (Avon Longitudinal Study of Parents and Children) study. They reported on prevalence of mild PCHI on the basis of consistent findings at all three test occasions. This methodology reduced the likelihood of a one-off assessment in a child with normal hearing but poor concentration being recorded as a case of mild PCHI. They found a prevalence of 0.4% for mild bilateral sensorineural hearing loss and 0.1% for bilateral high-frequency hearing loss giving an overall prevalence of 0.5% (CI 0.4, 0.8) at age 11 years. This is lower than commonly reported estimates from the USA[21] but similar to estimates from Australia.[22]

Auditory neuropathy spectrum disorder

Auditory neuropathy spectrum disorder (ANSD) is the label applied to clinical audiological test findings that indicate normal outer hair cell function as evidenced by the presence of otoacoustic emissions (OAEs) and/or the cochlear microphonic response and absent or severely abnormal auditory brainstem response (ABR). In earlier literature this was termed auditory neuropathy (AN); the new terminology was adopted in 2008.[23] This combination of test results suggests relatively normal activity in the outer hair cells but disruption of transmission at some point from the inner hair cells along the neural pathway to the brainstem. In some cases, neural firing may be occurring but with a lack of synchrony, so that no clear ABR is recordable. In some cases dys-synchrony may arise due to delayed maturation or myelination of the auditory pathway. The true prevalence of ANSD is not yet determined. It has been reported that up to 10% of all children with confirmed PCHI have auditory neuropathy. It is a condition found predominantly in the NICU population and it is considered relatively rare in the well-baby population.[23]

Temporary childhood hearing impairment

Temporary childhood hearing impairment due to otitis media with effusion (OME) is extremely common, with a point prevalence of 20% and a period prevalence in the under 5-year-olds of 80%.[4] The major risk factors are season, passive smoking, bottle-feeding, upper respiratory tract infections, admission to NICU as a newborn, day care and siblings having had OME. Refinement of risk factor analyses has indicated season, passive smoking, siblings having had OME and snoring and

mouth-breathing as the best indicators for persistence.[24] The TARGET (Trials of Alternative Regimens in Glue Ear Treatment) studies indicate effects of persistent OME on hearing difficulties, speech/language delay, disturbed sleep patterns, behaviour and (consequent on these) parental and child quality of life (see Chapter 13, Otitis media with effusion).[24]

THE RATIONALE POSITIVE FOR NEWBORN HEARING SCREENING

In this section, we will consider newborn screening mainly with respect to PCHI of moderate to profound degree.

The critical review (1997) of newborn hearing screening carried out as part of the UK's Health Technology Assessment programme[5] reviewed the evidence on the epidemiology, age at identification and intervention for PCHI, the performance of screens and services that were in place at the time and views of parents and appraised the options for detection of PCHI. The review concluded by recommending the introduction of universal newborn hearing screening for PCHI of moderate or worse degree in the better ear. Below is a brief summary of some of the evidence.

Outcomes

There is good evidence that outcomes in a number of domains are affected by bilateral moderate to profound PCHI. In most cases this is a severity-dependent effect, with greater effects for more severe impairments; there are, however, very great individual differences, with some children performing at levels appropriate to their age and others performing very poorly. These differences are not always a function of severity but will be a result of a range of intrinsic and extrinsic factors. One such factor is the age at identification, as well as habilitative support provided. The evidence of compromised outcomes associated with congenital PCHI comes from studies looking at communication skills,[25] literacy,[26] behaviour,[27] educational achievement,[28] mental health, [29] family dynamics[30] and quality of life.[27]

Age of identification

Prior to the introduction of universal newborn hearing screening the UK had a universal 8-month screen for childhood hearing impairment carried out by health visitors in community clinic settings and known as the health visitor distraction test (HVDT). With the introduction of newborn hearing screening this has been phased out; there is good evidence that it had poor sensitivity, poor specificity, high refer rate, low yield and was not cost-effective in terms of cost per case found.[5] The retrospective study of permanent childhood hearing impairment greater than or equal to 40 dBHL in children born between 1985 and 1993 and resident in Trent health region showed that the median ages at referral, confirmation of the impairment, prescription of hearing aids and fitting of hearing aids were, respectively, 10.4, 18.1, 24.4 and 26.3 months.[10] While much of the delay was clearly due to delays in the assessment process after referral, nonetheless the median age of screen referral for children with congenital hearing loss was little short of 1 year.

Benefits of early identification and intervention

There have been many observational studies that have reported benefits from earlier identification and intervention for PCHI[31, 32] but no true RCTs that address the question of whether universal newborn hearing screening (UNHS) results in earlier identification of PCHI, earlier intervention and improved outcomes. The only quasi RCT of the effect of newborn hearing screening on age at identification of PCHI and outcomes is the Wessex trial.[33] This study showed that birth during periods of UNHS was associated with confirmation of PCHI by 9 months of age and in turn this was associated with better receptive language scores but not with better speech at age 8 years.[33, 34] In 2008 the UNHS Task Force concluded that infants identified with PCHI through universal newborn screening have earlier referral, diagnosis and treatment than those identified by other means.[35] They concluded that the data from studies on language outcomes at school age strengthen the case for newborn screening but caution that effective methods of referral, follow-up and treatment are needed to maximize the effectiveness of newborn screening. Since then two population studies have confirmed that UNHS results in earlier identification and intervention and improved outcomes at age 3–5 years[36] and 7–8 years.[37] A further study found outcomes at age 3 years to be only weakly related to age at hearing aid fitting but for cochlear implant users the age at switch-on was significantly associated with better outcomes.[38]

The evidence around mild PCHI is equivocal. In a population study to determine the prevalence and effects of slight/mild sensorineural hearing loss in school children Wake et al.[22] concluded there was no strong evidence for adverse effects on language, reading, behaviour or health-related quality of life in children who are otherwise healthy and of normal intelligence. They did caution that further research is necessary to determine whether children with bilateral PCHI at the upper end of the slight/mild range experience adverse effects at the population level and, if so, whether they might gain more benefit than harm from systematic intervention. However, the optimal form of systematic intervention, including the role and benefits of amplification, remains to be determined.

Assessment and management

Some aspects of audiological assessment are easier in the first few months of life: for example, electrophysiological tests such as the auditory brainstem response, and habilitative procedures such as real ear measurements for hearing aid fittings can more readily be carried out during periods

of natural sleep. Perhaps more importantly, the earlier that parents and services know about the child's hearing impairment, the earlier decisions can be made about management including fitting of appropriate hearing aids, referral for cochlear implant, choice of communication methodology and provision of family support. In order to realize these advantages, screening and assessment must be viewed as the initial steps in a seamless family- and child-centred service with a multidisciplinary focus.

Costs

Bamford et al.[17] compared the NHS costs of NHSP (newborn) and HVDT (at 8 months of age) and concluded that NHSP appears to be a cost-effective strategy for hearing screening when compared to HVDT screening.

Cost-effectiveness

It has been argued that UNHS will have paid for itself within 10 years in terms of the long-term savings made in special education and social interventions. However, in a systematic review of cost-effectiveness Colgan et al.[39] identified only one study that found that UNHS could be cost-effective if early intervention leads to a substantial reduction in future treatment costs and productivity losses. Longitudinal data do not yet exist.

Parental wishes

Parents' views on the desirability and timing of newborn hearing screening received some attention in the literature prior to the widespread introduction of newborn hearing screening. Surveys show that around 80–90% of parents of children with permanent hearing impairment would have wanted it for their children if it had been available to them when their child was born.[40] It is also known that early identification tends to avoid the parental anxiety and anger that may be associated with delayed detection.[40, 41] Newborn hearing screening is widely accepted; data for the English programme show that less than 0.1% of families decline the screen.[18]

NEWBORN HEARING SCREENING

Case definition

While many North American screening programmes[42, 43] include babies with permanent mild and unilateral hearing impairments in their target group, the Newborn Hearing Screening Programme in England aims to identify all children with a moderate–profound PCHI in the better hearing ear.[17] As a by-product, the screen will also identify a number of babies who have unilateral and in some cases mild permanent hearing impairments, as well as temporary hearing impairments. The consequences of delay in identification are not well established in these infants, and optimal management is not clearly known. However, this is lack of evidence for effects rather than evidence of no effects, and research is needed to identify best practice for the early management of congenital permanent mild and unilateral hearing impairment as well as early management for temporary hearing impairments.

Current screening tests

The tests available for newborn hearing screening are automated otoacoustic emissions (AOAEs) using either transient or distortion product otoacoustic emissions or automated auditory brainstem response (AABR). Otoacoustic emissions reflect the activity in the outer hair cells of the cochlea, while AABR measures the neural response from the brainstem. Both types of test are available in portable hand-held screening instruments that employ automated detection algorithms to determine the presence or absence of a response and thus screening staff are not required to make any judgements about the response. Most screening programmes use a two-stage protocol (either OAE followed by AABR if required or two-stage AABR). The OAE is quick, minimally invasive and consumable costs are relatively low compared with AABR. The disadvantages are that it can be affected by the presence of fluid/debris in the outer or middle ear and will also miss neonates with auditory neuropathy. However, auditory neuropathy is predominantly found in the NICU/SCBU population and thus AABR is the method of choice in the NICU/SCBU population.

In the English NHSP screening is carried out using standard techniques and protocols[44, 45] and with equipment that has been approved for use within the programme. There are separate protocols for well babies and babies who have spent 48 hours or more in NICU/SCBU.

Well babies follow a two-stage two-technology protocol; the first stage is a transient AOAE screen, with a maximum of two attempts, followed by an AABR screen if required. A pass in both ears using AOAE, or a pass in both ears on AABR, constitutes an overall screen pass. **Babies cared for in NICU or SCBU for more than 48 hours** undergo a transient AOAE screen and an AABR screen. Those that fail the AABR screen in one or both ears are considered to be screen referrals and are referred for audiological assessment. Babies that pass the AABR screen in both ears and fail the AOAE screen in both ears are included in the risk-factor group and receive a follow-up at 8 months.

The most commonly used model in the English NHSP is a hospital-based screen employing a team of dedicated screeners performing the screening tests on newborns in the maternity unit before discharge. This is backed up by a recall clinic for the babies missed by the initial screen. In some areas a community-based screening model is used for well babies, with screening performed in the home or at local clinics.

Newborn hearing screening is also implemented in Wales, Scotland and Northern Ireland. These programmes also fall under the remit of the UK NSC. The details of their implementations differ in some respects from the English programme. Details can be found via the NSC website.[1]

High-risk screening

The high proportion of cases with risk factors led, in the early 1990s, to the widespread introduction of high-risk or targeted newborn screening in which attempts were made to screen all those babies (around 10% of the birth cohort) with risk factors, in order to achieve early identification for the 60% of true cases of congenital permanent impairment. However, in practice there are a number of difficulties with high-risk newborn hearing screening. The use of the family history risk factor is difficult to implement effectively[46] and thus the proportion of the target population identified by at risk screening was rarely above 40%.[5] Barker et al.[47] carried out a population audit of the effectiveness of stand-alone NICU screening compared with NICU screening as part of a universal screen and showed better performance in the latter case as measured by screening coverage, age of detection, loss to follow-up and positive predictive value of a refer result. More importantly, some 40–50% of babies born with permanent hearing loss demonstrate no risk factors. Numerous studies agree that around half of all affected infants have no risk factors at birth and thus would be missed by even the best-performing high-risk newborn hearing screening.[5]

Performance of universal newborn hearing screening

The NHSP in England was fully implemented in April 2006. Since then coverage has gradually improved and for the 2015/16 birth cohort 98.1% of babies completed screening by 4 weeks corrected age and 99.2% by 3 months. The refer rate has been relatively constant at 2.5% with 0.5% referring bilaterally. The yield for bilateral PCHI has been shown to be 1.01/1000 and the median age of identification for those screened by the programme is currently around 7 weeks.[18]

Parental anxiety

The prospect of the parental anxiety that might be engendered as a result of newborn hearing screening and in particular around false-positive results had been a cause for concern prior to the implementation of the screen. During implementation the NHSP in England developed a number of processes for ensuring high levels of information for mothers/parents, including a national screener-training programme, training and information sessions for other professionals, plain English information leaflets and DVDs for parents and informed parental consent to the screen. The detailed evaluation of Phase One of the English programme[17] indicated that, although referral for diagnostic tests has a small but significant effect on mothers' emotional well-being in the first 3 weeks after screening, the effect is below the cut-off for clinical concern. This small but significant emotional distress following recall for diagnostic tests after the screening is no longer evident at 6 months. The evaluation further concluded that ensuring good knowledge of possible reasons for referral seems to be protective against anxiety and newborn hearing screening does not cause more emotional distress than a test conducted some months later in infancy.[17] In the years since full implementation of the newborn screen in England parental anxiety has not emerged as a significant cause for concern.

Lost to follow-up

Lost to follow-up is an important consideration; there is little point in running a screening programme if the families of screen-positive babies are not willing to engage with diagnostic services and early intervention programmes. In the United States only slightly more than half of the infants who refer on newborn hearing screening receive follow-up.[48] In the English screening programme follow-up rates are much better; 87% of screen referrals have entered follow-up by 4 weeks and 95% by 6 months of age.[18, 49] Clearly there is a different context with services free at the point of use and a national programme and information system to track babies through screening and follow-up and record audiology results.

Quality assurance

There is an ethical duty within a screening programme to ensure not only a good quality screening service but also that good quality follow-up services are in place. The NHSP in England developed quality standards that include the screening pathway but also the follow-on diagnostic, medical, habilitation, early intervention and family support services.[50] These standards have been used as the basis for a national quality assurance programme. The quality and effectiveness of audiology services responsible for the electrophysiological assessment for babies that refer from newborn screening is pivotal to achieving early identification and intervention. Rigorous protocols and guidelines for these early assessments have been extensively developed alongside the implementation of the screening programme.[44]

THE SCHOOL-ENTRY SCREEN

Although there is a long history of school-entry hearing screening in the UK dating back to the 1950s, there has been little systematic evaluation of the benefits and there remains confusion about its aims and definition of the target condition. Apart from referring children with progressive and acquired permanent hearing loss that have not been picked up by parental observation and responsive services, the school-entry screen also has the potential to identify children with mild and unilateral hearing loss, as well as high-frequency hearing loss and other hearing losses with unusual configurations.

A Health Technology Assessment (HTA) review in 2007[51] found that a school-entry hearing screening is widely implemented, coverage is around 90% (in state schools), referral rates are high (8%), methods and referral criteria are highly variable and there is poor recording of data and little audit or quality assurance. The review concluded that, while screening for PCHI at school entry meets all but three of the requirements for

a screening programme, screening for temporary hearing impairment fails to meet at least six.

The current NSC policy acknowledges that, with the introduction of newborn screening, most cases will be identified before school entry; however, there will be some cases that were missed or have developed after the test. The current recommendation is that screening for hearing impairment in school-age children should continue while further research is undertaken.[1]

SURVEILLANCE

Surveillance for childhood hearing impairment is of considerable importance:

1. Newborn hearing screens will not find all those with preschool permanent hearing loss because of acquired, late-onset and progressive hearing impairment.
2. Any screening programme will miss some true cases.
3. Children with mild hearing loss and some with high-frequency hearing loss will not be identified by the screen.
4. Infants and children move in from countries where newborn hearing screening is not available.
5. Surveillance is a more justifiable approach to identification of children with persistent OME than a screening programme.

In an effort to identify children in category 1 above, many newborn hearing screening programmes have historically adopted regimes of targeted surveillance for babies who pass the screen and have certain risk factors. More recently, some programmes have questioned whether this is a useful service model.[52, 53] A recent analysis of data from English NHSP[54] showed that much of this risk factor-based surveillance is not effective and is now only recommended for babies that pass the screen with the following risk factors:

- syndrome (other than Down) associated with a hearing loss
- NICU with refer in both ears at OAE and pass in both ears at AABR
- craniofacial anomaly
- Down syndrome
- congenital infection.

Audiological assessment should always be carried out following recovery from meningitis, extracorporeal membrane oxygenation (ECMO), skull fracture and hyperbilirubinaemia.[55] Routine audiological monitoring should be offered to specific groups of children with a high risk of otitis media with effusion including children with Down syndrome and cleft lip and palate.[56, 57] Surveillance policies should encourage services to be highly responsive to parental or professional concern about a child's hearing or their development of auditory, vocal or communicative behaviour; where concern is identified, an age-appropriate audiological assessment should be carried out. The importance of ongoing surveillance by health visitors, family doctors, community health teams, as well as parents (reinforced by appropriate checklists such as those given to parents shortly after the birth of their child), should not be underestimated.

Otitis media with effusion has a high prevalence between 1 and 7 years of age. Screening for either the pathology or the consequent hearing impairment fails to meet the criteria for screening programmes outlined above because of its fluctuating nature, high remission rate and uncertainties over treatment.[58, 59] However, it can have an important impact on children's lives and development in persistent cases. Some sort of surveillance system needs therefore to be in place for identifying and intervening with those 5–10% of cases that have OME with a persistence or severity likely to interfere with development. It has been shown that the use by family doctors of a simple checklist and a training video significantly improves the positive predictive value of their referrals.[24]

FUTURE RESEARCH

- More evidence is needed on the medium- and long-term outcomes for children identified with PCHI and on the predictors for better outcomes.
- Further research is needed concerning the prevalence, aetiology, outcomes, diagnostic and habilitative options for children with auditory neuropathy spectrum disorder.
- Currently, some children with mild and unilateral hearing impairment will be identified as a by-product of newborn hearing screening for permanent bilateral hearing impairment of ≥40 dB HL. More research is needed about the prevalence, effects, outcomes and habilitative options for these children.
- There is evidence to show that progressive and acquired permanent childhood hearing impairment is more prevalent than previously thought. Confirmatory population-based prevalence data are needed together with continued assessment of the evidence on the risk factors to inform surveillance programmes.
- The school-entry screen requires a more extensive evidence base to enable evaluation of its effectiveness.

KEY EVIDENCE

- At least 1 in 1000 children is born with permanent bilateral hearing impairment ≥40 dB HL.
- If permanent bilateral congenital hearing impairment is identified before 6 months of age and habilitation started soon thereafter, the adverse effects are lessened.
- The prevalence of permanent bilateral hearing impairment ≥40 dB HL increases through childhood although the final prevalence figure is not yet certain; parents and professionals must continue to be appraised of this and surveillance systems and responsive services must be in place.
- Newborn hearing screening of all babies is the most cost-effective method of delivering early identification of congenital permanent hearing impairment of at least moderate or greater degree.
- More evidence is required on the outcomes for children with permanent mild or unilateral hearing impairment, and on alternative approaches to management.
- The evidence for school-entry screening is equivocal.
- Identification of persistent OME cases depends upon good surveillance systems in primary care and responsive services.

KEY POINTS

- Newborn hearing screening of all babies is the most effective and cost-effective way to identify congenital hearing loss.
- Audiology and screening services must work together to ensure rapid follow-up of screen referrals. This facilitates accurate audiological assessment. Such rapid follow-up, together with good-quality information, minimizes family anxiety.
- Audiology services must maintain and develop expertise in early audiological assessment techniques to enable early confirmation (or otherwise) of PCHI in babies referred from newborn hearing screening.
- Good quality services for true-positive cases based upon informed choices for parents are central to screening programmes at any age, but particularly for newborn screening.
- Management of true-positive cases involves close cooperation between health, education and social services.
- A surveillance programme must be in place to help identify late-onset and acquired hearing losses, backed up by fast responsive services.
- Parents and professionals in primary care need to be alert to the presence of persistent OME in some children.

CHAPTER 9

HEARING TESTS IN CHILDREN

Glynnis Parker

SEARCH STRATEGY

Data in this chapter may be updated by a Medline search using the keywords: audiometry/child and hearing test/child. Further information was accessed on the websites of the British Society of Audiology (BSA) (http://www.thebsa.org.uk/) and the American Speech-Language-Hearing Association (ASHA) (http://www.asha.org/).

INTRODUCTION

It is essential that suspected hearing loss in young children is promptly investigated. Accurate assessment of hearing is fundamental to diagnosis, investigation and rehabilitation. The techniques applicable to adults and older children are often inappropriate for the young child and for the older child or adult with special needs, particularly learning disability. Skilled testing by trained personnel in a suitable test environment is essential. The focus of this chapter is on those tests that require skilled observation and recording of the child's 'functional' responses to speech or 'non-speech' sound stimuli – often referred to as behavioural hearing assessments. The more complex evaluations utilized for pre- and post-assessment of children undergoing cochlear implantation are explored elsewhere (Chapter 11).

Effective assessment includes involving the family in a culturally and linguistically appropriate manner, providing a clear, sensitive explanation of the procedures and outcomes, supported by written information as available. A thorough assessment may require multiple sessions.

ELECTROPHYSIOLOGICAL TESTING

Key developmental age: 0–6 months, up to adult if appropriate

Electrophysiological techniques including otoacoustic emission (OAE), auditory brainstem response (ABR) and cortical evoked response audiometry (CERA) are discussed in Chapter 8, Hearing screening and surveillance, and Chapter 52, Evoked measurement of auditory sensitivity. These methods are mainly employed in newborn screening (see Chapter 8) and diagnostic testing of infants in the first 6 months.[1–4] They can also prove of value in children of any age when behavioural testing has failed to produce reliable results, in particular those with severe learning or communication difficulties.[5] Accurate assessment may require sedation or general anaesthesia. Electrophysiological techniques are also used to confirm hearing thresholds, for example, prior to cochlear implantation or where non-organic factors are suspected. While electrophysiological testing has the advantage of being objective in terms of the child's response, behavioural and

speech discrimination testing remain the only functional measures for assessing the complete auditory system.

BEHAVIOURAL OBSERVATION AUDIOMETRY

Key developmental age: 0–6 months

In behavioural observation audiometry (BOA), changes in activity are observed in response to a sound stimulus. Response behaviours include eye widening, eye blink (auropalpebral reflex), alteration in sucking response, arousal from sleep, startle or shudder of the body or definite movement of the arms, legs or body. From 4–7 months, lateral inclination of the head towards the sound or a listening attitude or stilling may be observed. The test is usually performed with the child cradled in the parent's lap or in an infant seat. The child's attention may be lightly engaged in front by a distractor. The sound stimulus may be presented for <2 seconds, in a horizontal plane, 15 cm from the child's ear, out of peripheral vision, or delivered via insert earphones. The distractor observes evidence of a response. A range of sound stimuli may be employed, including voice or noisemakers but ideally calibrated narrow-band, warble tones or ling sounds.[6,7]

Reliability as a diagnostic test is obviously a concern. A wide variability in judgement of response between testers due to misinterpretation of random movements and a tendency to underestimate hearing thresholds has been demonstrated.[8] Attempts have been made to reduce observer bias by use of video recording of the procedure and scoring the playback without knowledge of the sound or no sound trials.[9]

The use of BOA in infants under 6 months has been largely superseded by the availability of electrophysiological techniques. However, soundfield BOA may be of particular value in the verification of aided responses in infants, or in infants with a diagnosis of auditory neuropathy spectrum disorder when ABR is a poor indicator of functional hearing levels (see Chapter 69, Auditory neuropathy spectrum disorder and retrocochlear disorders in adults and children). It has the merit of allowing parents to participate in the assessment and witness their child's responses, leading to better understanding and acceptance of their child's hearing loss. BOA may have a continuing role in the assessment of older children with learning disabilities who have not reached an appropriate developmental stage for other means of assessment.

VISUAL REINFORCEMENT AUDIOMETRY

Key developmental age: 5-36 months

Visual reinforcement audiometry (VRA) incorporates the principle that young children can be trained by operant conditioning to produce a localizing turn to a visual stimulus in response to a sound stimulus. A technique of conditioned orientation reflex (COR) audiometry was initially described by Suzuki and Ogiba[10] and was further developed by Liden and Kankkunen[11] who introduced the term 'visual reinforcement audiometry'. Further developments and modifications to the technique have been described.[12,13] VRA is now established as a standard technique within the test battery for hearing assessment in preschool children and is generally suitable for infants once they have reached the developmental stage of being able to sit unsupported or with minimal support, i.e. at 5–7 months. VRA has largely replaced the use of the infant distraction test (see below) as it has become more widely available and has been demonstrated to generate more auditory-evoked head turns than an unrewarded sound stimulus and delays habituation so that the assessment is more likely to be completed.[14] The method is described with reference to the British Society of Audiology: Recommended procedure – Visual Reinforcement Audiology[15] and Widen et al.[16]

Test arrangement

The test room should be sound-treated to ensure low levels of ambient noise (ISO 8253),[17] which should be verified using a sound level meter. It should be adequately sized (recommended minimum of 6 m × 4 m), ideally with the ability to dim the lighting to permit enhancement of the illuminated vision reward. It may be partitioned to provide an observation area with a one-way window, with access to a communication system between the rooms, such as a radio link. A suitable arrangement is shown in **Figure 9.1**. If, however, this facility is not available, it is still possible to perform the test within one room, provided the tester operating the audiometer minimizes the distraction to the child and does not provide any additional clues. The child is seated on the parent's lap or on an infant seat or chair in front of a low table, with the parent seated slightly behind. A second tester may sit on the other side of the table or adjacent to the child to provide low-level play activity. For soundfield testing, the loudspeakers should be placed at 90° from the child and at the same height as the child's head at a distance of at least 1 m from the ear. Frequency-specific calibration of the sound signal from a test point equivalent to the child's head position is essential. Alternatively, a calibrated signal may be presented via insert earphones using foam tips or the child's own ear moulds, if available. This has the advantage of potentially providing more precise ear-specific response thresholds and even offers an opportunity to introduce masking by appropriate presentation of narrow-band noise in the contralateral ear. This is particularly valuable in amplification selection and setting.[18] A standard bone conductor may also be used in conjunction with VRA to differentiate between a conductive and sensorineural hearing loss.

Visual reinforcers are generally placed adjacent to or above each speaker. Facility should exist to move the reinforcer closer to the child to enhance reinforcement if indicated by visual ability or developmental status.

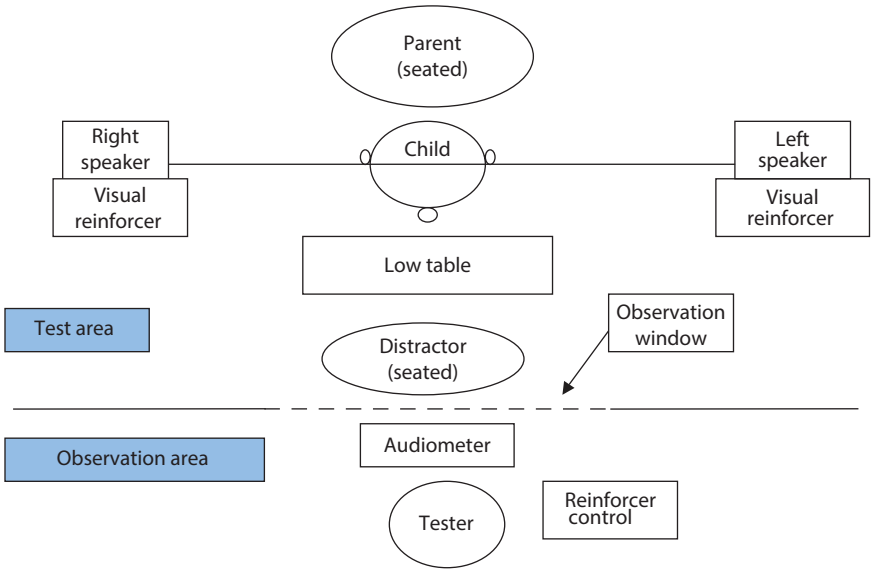

Figure 9.1 Test arrangement for visual reinforcement audiometry.

The reinforcer acts as a reward and therefore increasing the attractiveness or appeal to the child and introducing variety is likely to sustain interest and reduce habituation. Commercially available reinforcers include toys with eyes that light up and puppets in darkened glass cabinets which illuminate and dance. Monitors showing appropriate video displays can also be effective.[19, 20] The reinforcer is generally remotely activated by the tester as required.

Test method

Using the arrangement as described above, the first task must be to establish the conditioned response. Having drawn the child's attention to the front by gentle play activity on the table, a suprathreshold auditory signal should be presented concurrently with the visual reward. Appropriately calibrated frequency modulated (warble) tones, ling sounds or narrow-band noise (NBN) stimuli may be employed via soundfield, insert earphone, headphone or bone conductor, according to the clinical priority. For example, for a child with probable near-normal hearing, one might start with a 2 kHz warble tone at 60–70 dBHL, presented for 2–3 seconds. The child may turn to locate the sound (orientation response) and thereby view the activated reinforcer but, if necessary, the child's attention should be directed towards it. This sequence is repeated several times. The sound stimulus should then be presented alone and the reinforcer only activated after the child has produced an appropriate turning response. Praising the child and making it a game will further help to reinforce the response. If this can be reliably repeated two or three times, operant conditioning has been established. Children under 1 year or those with learning difficulties may take longer to successfully condition. If it appears that the initial auditory stimulus may be inadequate, this can be cautiously increased or a different frequency or vibrotactile stimulus used. NBN stimuli may be more effective in initially establishing the conditioned response,[21] but Thompson and Folsom[22] demonstrated that in VRA, unlike distraction testing, the complexity of the signal, including the bandwidth, had no effect on response rate once the child had been correctly conditioned.

Once the child has demonstrated successful conditioning, the aim is to establish the minimal response level (MRL) for each frequency, as prioritized by the clinical situation, bearing in mind that the child's cooperation may fail at any time. A typical order of stimulus presentation could be: 2 kHz – 500 Hz – 4 kHz – 1 kHz or 1 kHz – 4 kHz – 500 Hz – 2 kHz. Additional frequencies may be included if clinically relevant, for example 0.25 kHz, 3 kHz, 6 kHz, 8 kHz. A flexible descending/ascending (10 dB down, 5 dB up) principle, similar to that used in pure tone or play audiometry (see below), should be applied, although the increments and decrements in intensity (i.e. the steps up and down) may be increased to hone in on the response threshold. The duration of the signal is usually 2–3 seconds. One reliably obtained MRL is more valuable than a number of 'maybes'. Variable inter-trial intervals and 'no sound' control trials should be included to verify a true response and particular scrutiny is required in the event of frequent 'checking behaviour'.[23] If the child becomes bored and less responsive, it may be appropriate to recondition the child using suprathreshold stimuli and/or change the stimulus type or visual reward or, indeed, have a short break. Children generally respond well to praise and encouragement – the assessment should be a fun and enjoyable experience for the child and parent while maintaining objective accuracy. The outcome of each valid presentation and 'no sound' trial should be recorded in chart form, specifying the sound source, frequency range and intensity. A tick or a cross may be used to indicate whether a response was observed The MRL is regarded as the quietest level at which two out of three clear responses were recorded for each particular sound stimulus. The ability to localize the sound source correctly may be assessed, for example using a soundfield high- and low-frequency NBN

stimulus 30 dB above the MRL: difficulty with localization may indicate an asymmetric hearing loss although the converse does not necessarily apply.

Relevant observations which may affect the test reliability, such as alertness or cooperation of the child or subject-generated noise, should be recorded and taken into consideration when interpreting the results of the assessment. Responses recorded on soundfield testing are approximately +10 dB relative to adult thresholds and MRLs down to at least 25 dBHL on soundfield testing are generally regarded as compatible with satisfactory binaural hearing.[24, 25] Correction factors using insert earphones have been estimated for infants with normal hearing assessed by VRA relative to adult thresholds and are currently recommended as +15 dB at 0.5 kHz and 1 kHz and +5 dB at 2 kHz and 4 kHz.[15] Primus[26] found test–retest reliability to be good with 50% repeatability within 10 dB. Widen et al.[16] demonstrated that MRL for at least four frequencies were successfully recorded in more than 90% of over 3000 infants aged 8–12 months, tested using VRA.

THE DISTRACTION TEST

Key developmental age: 6–18 months

The test is based on the principle that the normal response observed when sound is presented to an infant is a head turn to locate the source of sound. The test is suitable at 6–18 months, corresponding to the stage when the child can sit erect unsupported and perform head turns in a horizontal plane. An appropriate allowance should be made for prematurity. Habituation is increasingly likely to occur after 12 months, although the technique may prove to be useful in older children with learning or communication difficulties where other methods have been unsuccessful.

The infant distraction test was first described by Ewing and Ewing in 1944,[27] but was subsequently modified by McCormick[28] who placed particular emphasis on the use of frequency-specific, calibrated sound stimuli. For many years the distraction test was used as a tool for screening for hearing impairment in infants around 7–9 months, but such programmes have generally been withdrawn in favour of electrophysiological screening in the newborn period[1, 2] (Chapter 8, Hearing screening and surveillance). The use of distraction testing by audiologists has also been largely discontinued in favour of VRA.[14] Nevertheless, it remains a valuable diagnostic technique when used by trained, experienced testers in appropriate settings when other methods are unavailable, unsuitable or unsuccessful. The test is described with reference to McCormick[29] and guidelines published by the British Society of Audiology.[30]

Test method

The test environment is similar to that used for VRA. Two testers are required, one to present the sound stimuli out of vision and the other to control the infant or child's attention in the forward direction (the distractor). The latter should be responsible for directing the test. The arrangement is shown in **Figure 9.2**. The child sits on the parent's knee, facing forward and erect, lightly supported around the waist. The distractor directs the attention of the child to a simple activity usually performed on a low table. Suitable examples include spinning a brightly coloured object, showing a small toy or blowing bubbles. In the classic distraction test described by McCormick,[29] the item is covered by the hands which maintain a fine attention control by moving the fingers slightly. The sound stimulus is presented by the second tester, half a second after the item is covered. The distractor observes the child's response.

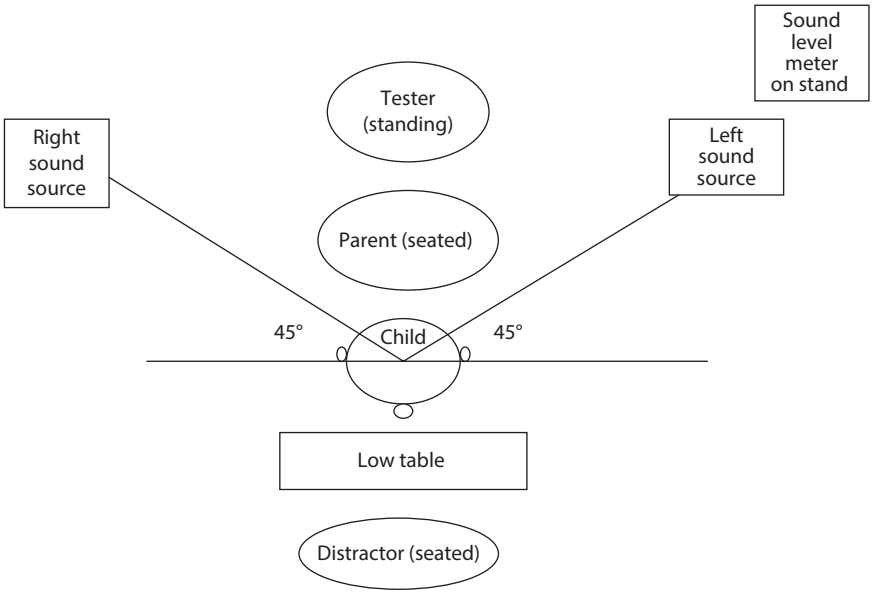

Figure 9.2 Test arrangement for the distraction test.

The second tester should be positioned strictly out of the child's visual field, which can be assumed to extend at least 90° to either side of the child's midline. The sound stimulus should be presented in the horizontal plane to the ears at an angle, set back 45° between 1 m and 15 cm from the child's ear. The shorter distance increases the head shadow effect, thereby increasing the sound stimulus on one side relative to the other. Evidence of asymmetric hearing levels may be indicated by a difference in response thresholds or difficulty in localizing the sound source. Particular care must be taken when presenting the sound close to the ear to avoid visual or tactile clues. The sound stimulus should continue up to 10 seconds if there is not an immediate response. During this interval, the distractor should maintain the fine attention control at the front until a response is observed.

The normal response expected is a full head turn in the direction of the sound. This may be rewarded by a smile or vocal praise or gentle touch from the second tester. Some warble tone generators incorporate a flashing light, which can be activated in response to the turn, providing an incentive to the child and thereby acting as a 'response reinforcer'. The child's attention should then be brought back to the front by the distractor.

A wide range of sound stimuli can be used to elicit a response, including voice (e.g. unforced 'S' = high frequency, or hum = low frequency), musical toys, calibrated high-frequency rattle, NBN or warble tones. Pure tones should be avoided due to the potential creation of standing waves, resulting in unpredictable sound levels. Responses to any sound stimulus may be valid, provided the intensity and the frequency spectrum, as delivered at the level of the ear, can be established. A sound level meter should be employed to check the intensity of the stimulus by accurately reproducing the sound and the distance from the ear. Although it has been demonstrated that infants are more likely to respond to wide-band sounds, this will inevitably provide less information regarding frequency-specific hearing as required for diagnosis and possible amplification prescription. Sound generators delivering calibrated narrow-band and frequency-modulated warble tones have been demonstrated to be effective at eliciting a response and are therefore generally preferred.[22]

Initially, a sound stimulus is presented which is anticipated to be likely to be suprathreshold, for example at 70 dB(A) in a child with probable normal hearing. A sound is then presented at the anticipated minimal response threshold, for example 30 dB(A). The intensity for sound-field testing is generally measured on the dB(A) scale, but this can be converted to dBHL if required, particularly for hearing aid prescription fitting – in practice the only correction factor required to the nearest 5 dB is +5 dB at 4 kHz.[17, 30]

There is no prescribed order for frequency and intensity of sound presentations. The number of reliable responses elicited by distraction testing may be limited, particularly in children over 12 months who may habituate to the test. It is therefore important to prioritize and focus on those thresholds which would be most valuable for each clinical situation but normally aim to include high-, mid- and low-frequency information. This, however, may need to be balanced against the benefit of varying the order and side of presentation simply to sustain the child's interest.

Variable intervals between presentations and control 'no sound' trials are essential for the validation of response thresholds in a distraction test and a scoring system should be employed in the same manner as for VRA (see above). Tactics such as increasing the interest of the distracting activity and/or maintaining that activity while the sound/no sound is presented may avoid 'clueing in' the child. This may be particularly helpful in children over 1 year. Evidence of visual, tactile or even olfactory clues must also be considered and addressed. The MRL is regarded as the quietest level at which two out of three clear responses are recorded for each particular sound stimulus. The MRL for distraction testing may be worse than for VRA and clinical judgement is required in interpreting the results.[14] Other observations such as the ability to localize the sound source correctly or any concerns about the test reliability should also be recorded.

TEST METHOD PITFALLS IN BOA, VRA AND DISTRACTION TESTING

Table 9.1 lists the most commonly encountered pitfalls in BOA, VRA and distraction testing and possible measures to avoid them.

PERFORMANCE TESTING (PLAY AUDIOMETRY)

Key developmental age: 2–5 years

The performance test was first described by Ewing and Ewing[27] as a transitional technique suitable for children from 2.5 years and in some cases younger, until cooperation with pure tone audiometry can be achieved. It follows the simple principle that the child is conditioned to wait for a sound and then to respond with a play activity. The test method is described with reference to McCormick.[29]

Test method

The child should be seated on a low chair adjacent to the parent in an uncluttered room with low levels of ambient noise.[17] A toy is placed on a low table in front of the child (Figure 9.3). Toys which involve a simple repetitive activity are most suitable, such as the classic 'men in a boat', balls on sticks, or pegs in a board. The conditioning sequence starts with the tester engaging the child's attention by holding the response item (e.g. the wooden man) poised waiting in front of the child. After a few seconds, a suprathreshold sound stimulus is presented and the tester responds by an appropriate activity, such as placing the man in the boat. This sequence is repeated several times,

TABLE 9.1 Pitfalls encountered in behavioural observation audiometry, visual reinforcement audiometry and distraction testing

Pitfalls	Avoidance measures
Attempting conditioning to sub threshold stimuli	Cautiously increase intensity of stimulus until a response is elicited
Visual, tactile, olfactory clues from parent, distractor or second tester	Critical observation of all parties 'No sound' control trials
'Checking' responses by child	Critical assessment of responses 'No sound' trials, if necessary take a break, or sustain distraction activity
Loss of interest in test, suprathreshold responses	Vary the sound stimulus Exchange roles of distractor or second tester Use broader band or more interesting sounds
Inaccurate estimation of frequency and intensity of stimulus	Use calibrated sound sources Measure accurately with sound level meter, trying to reproduce conditions
Extraneous noise, leading to false responses or only suprathreshold response	Use a sound-treated room with ambient noise <30 dB(A) Observe other auditory clues, e.g. clicking switch on warbler 'No sound' control trials

Figure 9.3 The performance test.

often supported by gestures such as a stop sign using the palm of the hand and a cupped hand to the ear to indicate listening. This has the advantage of avoiding dependence on spoken language. The child is then offered the response item and guided to wait and perform the task as shown. Vocal praise and possibly clapping should be used to reinforce a correct response. The number of repetitions required to successfully condition the child will depend on their age, developmental status and willingness to cooperate and in particular their ability to inhibit the response until the signal is detected. It may be necessary to increase the intensity of the signal or initiate conditioning using a vibrotactile stimulus.

Once the child has been successfully conditioned to perform the test without guidance, a flexible descending/ascending technique as described for pure tone audiometry (see Chapter 51, Psychoacoustic audiometry) can be applied to determine the MRL. While the MRL should be determined by a two correct responses out of three method, using the 10 dB down, 5 dB up technique, it may be appropriate to ascend and descend in larger steps to hone in on the threshold, as described for VRA (see above). The interval between presentations must be randomly varied to avoid a predictable rhythm. 'No sound' trials should be included. It may be necessary to reinstruct the child by guiding a few responses when the stimulus is changed or if the child appears to have lost concentration. It may also be necessary to introduce several changes of activity to sustain interest. This provides the tester with an opportunity to be adaptable and inventive and is part of the joy of audiology! Examples might include knocking the man off the table, flicking a small ball into a 'goal', or banging a drum. The aim is to be fun enough to motivate the child while being accurate enough to provide valid responses.

In the original description of the performance test, the signal used was a voiced 'go' (low frequency), or a sibilant 's' (high frequency).[27] When using voiced signals, it is essential that the face is totally outside the child's visual field and the mouth is shielded to prevent any awareness of air movement. The tester should therefore adopt a position similar to that described for distraction testing. Frequency-modulated warble tones with stimulus duration of 1–3 seconds are now the preferred option, providing low-, mid- and high-frequency-specific signals delivered by means of portable soundfield noise generators, loudspeakers, insert earphones (using the child's own ear moulds if available) or bone conductor, used in a similar arrangement to that described for VRA. The technique is particularly useful for recording aided soundfield responses. Whatever the signal, it is essential that the test conditions are reproduced accurately to calibrate the intensity delivered to the child's ear. The sequence of presentation should be determined by the clinical priority but would typically be 1 kHz–2 kHz–4 kHz–0.5 kHz then possibly 8 kHz, 0.25 kHz, 3 kHz and 6 kHz as indicated.

PURE TONE AUDIOMETRY

Key developmental age: 3 years onwards

The techniques employed in performance testing (play audiometry) naturally lead into pure tone audiometry as the child matures. This progression should be adapted to the individual child's ability and cooperation and to

the clinical priority. It may be possible, for example, to introduce a bone conductor before a child will tolerate headphones or, alternatively, a child who is accustomed to wearing hearing aids may comply with insert earphone audiometry via their ear moulds, as a progression from VRA. Insert earphones have the advantage of increasing transcranial attenuation reducing 'crossover' and of reducing the effect of ear canal collapse which may occur with supra-aural headphones. Again, it is important to sustain interest and concentration by the appropriate use of toys and praise.

The recommended procedures for pure tone audiometry[31] based on the Hughson and Westlake descending/ascending technique using 10/5 dB steps should be flexibility adapted (see Chapter 51, Psychoacoustic audiometry). There is no standard for the interpretation of results in children. Nielsen and Olsen[32] reported that it was possible to obtain at least six ear-specific air conduction thresholds from virtually 75% of 3-year-olds. An MRC multicentre otitis media study which examined a cohort of over 15 00 children found that there was only an improvement of 0.1 dB for bone conduction thresholds for each month of increase in age between 3 and 6 years. It was concluded that, by the age of 3 years, it should be possible to record hearing thresholds close to adult levels, if the child has conditioned adequately to the test.[33] The introduction of standard masking techniques, where appropriate, will depend on the child's cognitive developmental level and cooperation, but these may not be reliable until the age of 7 years.

AUDITORY SPEECH PERCEPTION TESTS

The ability to discriminate speech signals may be a valuable measure of functional hearing in children with normal to moderate degrees of impairment and is also increasingly used in the evaluation of more severely affected children supplied with hearing aids or cochlear implants. The test batteries developed for use in these latter situations are discussed elsewhere (see Chapter 51, Psychoacoustic audiometry). The tests described below represent a selection from a wide range available and are for use in more general clinical situations.

THE COOPERATIVE TEST

Linguistic developmental level: 18–30 months

The cooperative test is another test originally described by Ewing and Ewing[27] and requires the child to discriminate three different simple instructions, for instance having been handed a small toy, asked to 'give it to Mummy' or 'give it to teddy' or 'give it to baby'. Starting at a suprathreshold level, the voice is then dropped and visual clues removed by covering the mouth. A child with normal hearing may discriminate the instruction at 35–40 dB(A). This technique has been largely superseded by the more effective methods of assessing behavioural hearing thresholds such as VRA and by the more complex speech discrimination tests described below, but it may have some value if equipment and facilities are limited. It can obviously be adapted to suit different cultures and languages.

SPEECH DISCRIMINATION TESTS

Linguistic developmental level: 30 months onwards

A wide range of speech discrimination assessments are available and may be valuable in verifying hearing thresholds and in assessing the effectiveness of hearing aids or auditory implants.[34, 35] The choice of test will depend on the child's age, stage of linguistic development and home language and may be influenced by non-auditory factors such as access to language, specific language impairment and cognitive level.[36, 37] Several generations of toy and picture tests have been progressively developed and refined for the younger child including the Stycar test,[38] the Word Intelligibility by Picture Identification test (WIPI),[39] Northwestern University Children's Perception of Speech test (NU-CHIPS),[40] the Manchester picture test,[41] and the McCormick toy test,[42] which is widely used in the UK. This employs seven pairs of similar sounding nouns such as spoon/shoe or cup/duck, each represented by a small easily recognizable toy, placed on a table in front of the child in a quiet room, i.e. a closed-set assessment. Using live voice, the child is asked to 'show me the … spoon', etc. Having established an understanding, the voice level is dropped and visual clues removed by covering the mouth. The word discrimination threshold (WDT) is taken as the quietest level at which the child correctly identifies 80% of the toys including the paired consonants. For a child with normal hearing, this would be expected to occur at ≤40 dB(A). A digitized recorded version of the test is available which utilizes a small loudspeaker to deliver the instruction at variable intensities and this has been further developed to incorporate a scoring system using the ascending and descending principle to calculate the WDT, both in quiet and in the presence of a broadband noise signal. For children aged 2-5 years, a WDT at or less than 35 dB(A) in quiet is regarded as satisfactory, based on 71% correct responses for six reversals. The choice of words can be adapted for English as an additional language.[43, 44]

Further closed-set or 'forced-choice' speech test packages are available which examine more specific elements of consonant or vowel discrimination in quiet or in noise. In the Consonant Confusion Task (CCT)™, for example, the child is presented with nine sets of cards, each showing four pictures representing monosyllabic words containing the same vowel but different consonants such as cow/house/owl/mouse. The child is asked to point to the target word that they hear, presented at a calibrated level. Two of the four words in each set are repeated to reduce predictability. The percentage of correct responses can be calculated for each level and may be particularly valuable in verifying the effectiveness of a hearing aid programme.[45, 46] Other examples include the four alternative auditory feature (FAAF) test,[47] the imitative

test of speech pattern contrast perception (IMSPAC),[48] and the 'plurals test' which specifically assesses the ability to detect the word-final fricatives /s/ or /z/.[49]

Similar assessment tools are available in alternative languages.[50, 51]

Older children who have acquired appropriate linguistic skills, generally from around the age of 6–8 years may be compliant with formal speech audiometry, using open set tasks whereby they listen and repeat a word or sentence presented at a calibrated level in quiet or in noise to a single ear or binaurally. Original examples include the AB word list described by Arthur Boothroyd in 1968[52] and the BKB (Bamford-Kowal-Bench)[53] sentence list, which are widely used in children and adults and are described in Chapter 51, Psychoacoustic audiometry.

Monitoring tools using parental observation of auditory behaviour and language development are increasingly used to assess progress in children supplied with hearing aids and cochlear implants. Examples include LittlEARS® Auditory Questionnaire[54] for children under developmental age of 2 years and subsequently the Parents' Evaluation of Aural/Oral Performance in Children (PEACH)™ questionnaire.[55, 56]

HEARING ASSESSMENT IN CHILDREN WITH COMPLEX NEEDS

Approximately 30% of hearing-impaired children have an additional disability.[57] Children with global developmental delay have a particularly increased risk of hearing impairment and hearing assessment is therefore advocated for this group of children in addition to routine hearing screening.[58] However, this may be challenging and techniques must be appropriately adapted. For a child with complex needs, the test most suited to their developmental level rather than chronological age should be selected. Clear, simple demonstrations of conditioning tasks may require multiple repetitions to achieve understanding. In children with motor delay or physical disabilities, such as cerebral palsy, the required response must be tailored to the child's capability. In VRA, for example, it may be necessary to bring the visual reward closer and to accept an eye glance response. In distraction testing, a partial head turn, eye glide or stilling may be judged as an acceptable response provided it is reproducible and validated by 'no sound' trials. For performance testing and pure tone audiometry, the conditioning task may need to be modified, such as knocking a toy brick off a table with hands or feet, hitting a drum or observation of a reproducible body movement such as wriggling toes.

Visually impaired children are more likely to respond to familiar sounds or if the response is reinforced by a tactile reward such as puffs of air on the cheek.[59] The use of brightly illuminated reinforcers in a darkened room may facilitate VRA in the partially sighted.[15] Assessment of hearing in a child with autistic spectrum disorder may present a particular challenge, due to the characteristic self-directed behaviour and lack of shared attention, making interaction with the tester difficult, although the repetitive nature of performance testing may particularly appeal to some. Fear of the unfamiliar test room and staff may be addressed by building confidence over a number of visits. Pre-preparing the child by explanatory booklets or a personalized 'social story' may reduce the anxiety.[60, 61] Many children with autistic spectrum disorder have sensory processing issues resulting in sound sensitivity and care must be taken to provide reassurance and avoid distress.[62]

If the outcome of behavioural hearing assessment for a child with complex needs proves to be inconclusive, consideration should be given to objective electrophysiological measurement, which may require sedation or anaesthesia.[5]

BEST CLINICAL PRACTICE

- ✓ Be age-appropriate: use the test technique that is most suited to the child's age, developmental status and willingness or ability to cooperate.
- ✓ Be specific: know what you are testing. Calibrate the frequency and intensity of the sound stimulus.
- ✓ Be valid: reproducibility and use of 'no sound' trials are essential. Avoid other clues. Children can make good cheats.
- ✓ Be adaptable: non-standard techniques may be best in non-standard children.
- ✓ Be fun: children easily get bored and frightened. Their cooperation is required. Use toys and smiles – make it a game.

FUTURE RESEARCH

The only level 1 evidence and grade A recommendations cited in this chapter relate to the use of electrophysiological testing (ABR, OAE) for screening and diagnostic assessment in infants under 6 months of age.[1] Other test methods are essentially descriptive, having been progressively modified, based on expert experience and summarized in guidelines.[7, 15, 16, 30, 31, 35] While specific elements of the test protocols have been subjected to small-scale controlled studies,[12, 19–22, 43] the only large-scale studies available examine the feasibility of obtaining response thresholds using a test protocol, rather than its sensitivity or specificity.[16, 33] There is clearly a difficulty in performing blind controlled trials of obviously differing techniques. There are also no subject-specific definitive response thresholds available for comparison. Reliance is placed on intra- and inter-test/retest reproducibility, as an indication of accuracy.[8, 14, 16, 18, 23–26, 32, 36, 43, 54] Comparison of behavioural test response thresholds with subsequent pure tone audiometry thresholds cannot take account of fluctuating hearing levels during the intervening months or years.

There are therefore inherent challenges in conducting large-scale controlled trials. In the UK, emphasis has more recently been placed on establishing guidelines for good practice, promoting training and availability of equipment with the aim of improving equity of service.

KEY POINTS

- Accurate testing of hearing is essential in the diagnosis and management of childhood hearing loss.
- Testing and accurate assessment of the test results requires considerable skill and expertise.
- A 'menu' of tests is available depending on the child's age, the availability of expertise and the purpose of the test.
- More than one test method may be needed.
- Testing children with complex needs can be particularly challenging.

CHAPTER 10

MANAGEMENT OF THE HEARING IMPAIRED CHILD

Chris H. Raine, Sue Archbold, Tony Sirimanna and Soumit Dasgupta

SEARCH STRATEGY

Data in this chapter may be updated by a Medline search using the keywords: aetiology, deafness, hearing loss or hearing impairment, and child. The websites of the various associations shown in Box 10.1 are useful sources of information in this rapidly changing field.

INTRODUCTION

This chapter focuses on the general principles of the management of a child with stable or progressive sensorineural hearing loss including auditory neuropathy spectrum disorder (ANSD) (see Chapter 69, Auditory neuropathy spectrum disorder and retrocochlear disorders in adults and children).

Permanent childhood hearing impairment (PCHI) is defined as a confirmed permanent bilateral hearing impairment ≥40 dBHL (hearing level) averaged over the frequencies of 0.5, 1, 2 and 4 kHz in the better hearing ear. A PCHI can be conductive, sensorineural or mixed. The onset of hearing loss may be pre-natal, peri-natal or post-natal. The aetiology may be congenital or acquired.

The hearing loss may occur before (pre-lingual deafness) or after the child has acquired the ability to speak (post-lingual deafness). This distinction has important implications for education and management. Early identification and appropriate audiological, medical and educational intervention will help maximize the child's potential. Identifying and understanding the consequences of associated medical conditions, impairments and disabilities is also extremely important to provide the best opportunity for the child and the parents to make informed choices and plans for the future.

Earlier identification with universal newborn hearing screening (Chapter 8, Hearing screening and surveillance) is now practised in many developing -and most developed- countries. Improved audiological assessment techniques have provided a unique opportunity to confirm the exact nature and extent of the hearing loss within 8 weeks of birth, leading to very early habilitation with precise amplification and with diagnostic verification using well-developed and internationally

agreed techniques. Improved knowledge and understanding of aetiologies has made it possible to provide better information on the nature of the hearing loss, preventing deterioration in some cases and aiding identification of other system involvement, for example, retinitis pigmentosa in Usher syndrome and enlarged vestibular aqueduct in Pendred syndrome. Early confirmation of hearing loss, early amplification, early assessment of benefit from hearing aids, early understanding of important medical and aetiological factors, and early cochlear implantation have all led to much better audiological, educational and longer-term outcomes. This progress depends on multidisciplinary working, agreed professional guidelines, and the involvement of families and those with a hearing loss themselves.

The terms 'deafness' and 'deaf' are used in this chapter to cover moderate, severe and profound hearing loss. This is not to imply that mild hearing losses should be ignored. The severity of hearing loss or deafness may not necessarily have a direct relationship with disability (see WHO definition of impairments, activity limitations, and participation restrictions). These terms are discussed in a chapter on the special needs child (Chapter 5, The child with special needs).

According to the WHO[11] there are 466 million people worldwide with disabling hearing loss, i.e. hearing loss greater than 40 dB in the better hearing ear in adults (432 million) and a hearing loss greater than 30 dB in the better hearing ear in children (34 million). The majority live in the middle- and low-income countries of South Asia, Asian Pacific and sub-Saharan Africa.

CLASSIFICATION AND MEASURES OF HEARING LOSS

Although dBHL is an internationally agreed measure, there are differences in the classification and categorization of hearing loss between various organizations. It is important to describe which classification is employed and the frequencies used to average so that comparison can be made.[12–16] Classification of hearing losses by hearing thresholds is shown in **Table 10.1**.

TABLE 10.1 Four commonly used systems

dB HL	WHO	NHSP	BSA[13]	ASHA[12]
Normal	≤25	≤20	<20	–10 to 15
Slight	26 to 40			16 to 25
Mild		21 to 39	20 to 40	26 to 40
Moderate	41 to 60	40 to 69	41 to 70	41 to 55
Moderately severe				56 to 70
Severe	61 to 80	70 to 94	71 to 95	71 to 90
Profound	≥81	≥95	>95	>90

EPIDEMIOLOGY

The incidence of a child born with a PCHI is typically quoted as 1 per 1000 births. Fortnum et al.[17] reported an adjusted prevalence of 1.07/1000 and this may rise to 2.05/1000 amongst children 9 years or older,[17] as PCHI may present well after birth as a result of late onset congenital progressive or non-progressive hearing loss, either conductive or sensorineural. According to the NHS Newborn Hearing Screening Program (UK) from December 2012 to December 2013, the incidence of confirmed *bilateral* PCHI was 0.76%, while the figure for *unilateral* loss was 0.46%. About one third of all children with PCHI have severe to profound sensorineural hearing loss (SNHL). About one third of children with sensorineural PCHI will have a simultaneous vestibular weakness. Figures are considerably higher in developing countries.

AETIOLOGY

Hearing loss in a child may be present at birth ('congenital') or may develop after birth ('acquired'). Management of a child with confirmed PCHI requires a holistic approach for optimal audiological care with supporting services for the child and the family and also appropriate medical management, which includes offering and arranging necessary investigations to determine the aetiology. Most children with a PCHI have a SNHL. Those children who have a purely conductive hearing loss may have some congenital conditions, such as ossicular abnormalities and bilateral aural atresia. (Chapter 12, Congenital middle ear abnormalities) Some may have a mixed hearing loss, many have a fixed loss but others have a progressive hearing loss. In children, especially during the first 5–6 years of life, acute otitis media (AOM) and middle ear effusions ('glue ear') are common with a much greater prevalence than PCHI. Children with PCHI especially with craniofacial abnormalities are also vulnerable to AOM and to middle ear effusions, making their hearing loss temporarily worse. This is even more important in those who have unilateral hearing loss as their ability to hear is significantly compromised during such episodes (see Chapter 13, Otitis media with effusion and Chapter 14, Acute otitis media).

Infections causing a hearing loss include congenital conditions such as rubella and cytomegalovirus (CMV), and acquired childhood infections such as mumps, measles, meningitis and chronic otitis media. In the developed world, deafness from meningitis is declining because of HiB and Meningitis C vaccination and over half of children with PCHI have a genetic cause for their deafness.[18]

The causes of PCHI are shown in **Table 10.2**.

Genetic causes

Hereditary or genetic hearing loss results from aberrations in the coding function or processing of human DNA. In the Western world genetic factors are now thought to be responsible for over half the cases of congenital SNHL but with more genetic tests becoming available, and the pressure to perform them, this proportion is expected to

TABLE 10.2 Causes of permanent childhood hearing impairment

Causes of hearing impairment		
Congenital disorders		
Genetic	Syndromic	Autosomal recessive
		Autosomal dominant
		X-linked
		Mitochondrial
	Non-syndromic	Autosomal recessive
		Autosomal dominant
		X-linked
		Mitochondrial
Non-genetic	Congenital rubella syndrome	
	Cytomegalovirus First-trimester maternal infections (viral or bacterial)	
	Congenital syphilis Toxoplasmosis Hyperbilirubinemia Low birth weight Birth asphyxia Drugs during pregnancy, such as aminoglycosides, some antibiotics, anti-epilleptic drugs, cytotoxic drugs, antimalarial drugs, and diuretics. Maternal substance abuse e.g. alcohol, recreational drugs Maternal endocrine disorders e.g. diabetes mellitus, thyroid dysfunction 'Third window' disorders (see text, aetiology often unknown, may be congenital or acquired)	
Acquired causes		
Perinatal	Hypoxia	
	Hyperbilirubinemia	
Postnatal	Infections	Chronic otitis media
		Herpes Meningitis
		Mumps
		Measles Toxoplasmosis Varicella
		HIV
	Ototoxic drugs	
	Trauma / noise exposure	
	Neoplastic disease Foreign bodies in ear canal Immune system disorders	
Idiopathic		

rise significantly.[8, 19, 20, 21] About 70% of children with PCHI are considered to be non-syndromic (**Figure 10.1**) and the remaining 30% have one of a large variety of syndromic conditions.[22] Genetic hearing loss is mainly of monogenic phenotype. The majority ≈80% are autosomal recessive typically presenting pre-lingually, and some 20% are autosomal dominant, more typically presenting as progressive or post-lingual[23] with about 1% with X-linked or mitochondrial inheritance in which the trait is passed through the maternal lineage (see Volume 1, Chapter 2, Genetics in otology and neurotology).[24]

The gene mutations related to non-syndromic hearing loss are currently reported on web pages such as http://hereditaryhearingloss.org[5] and http://ghr/nlm.nih.gov.[4] Identification is labour intensive and expensive but with advancement in techniques new platforms are being applied.[25] Screening with Sanger sequencing for *GJB2* mutations is commonly performed, as they account for about 20% of autosomal recessive non-syndromic hearing loss (ARNSHL) for families in Northern Europe. Mutations in the pendrin gene *SLC26A4* are the next most frequent cause of ARNSHL.[21] The carrier

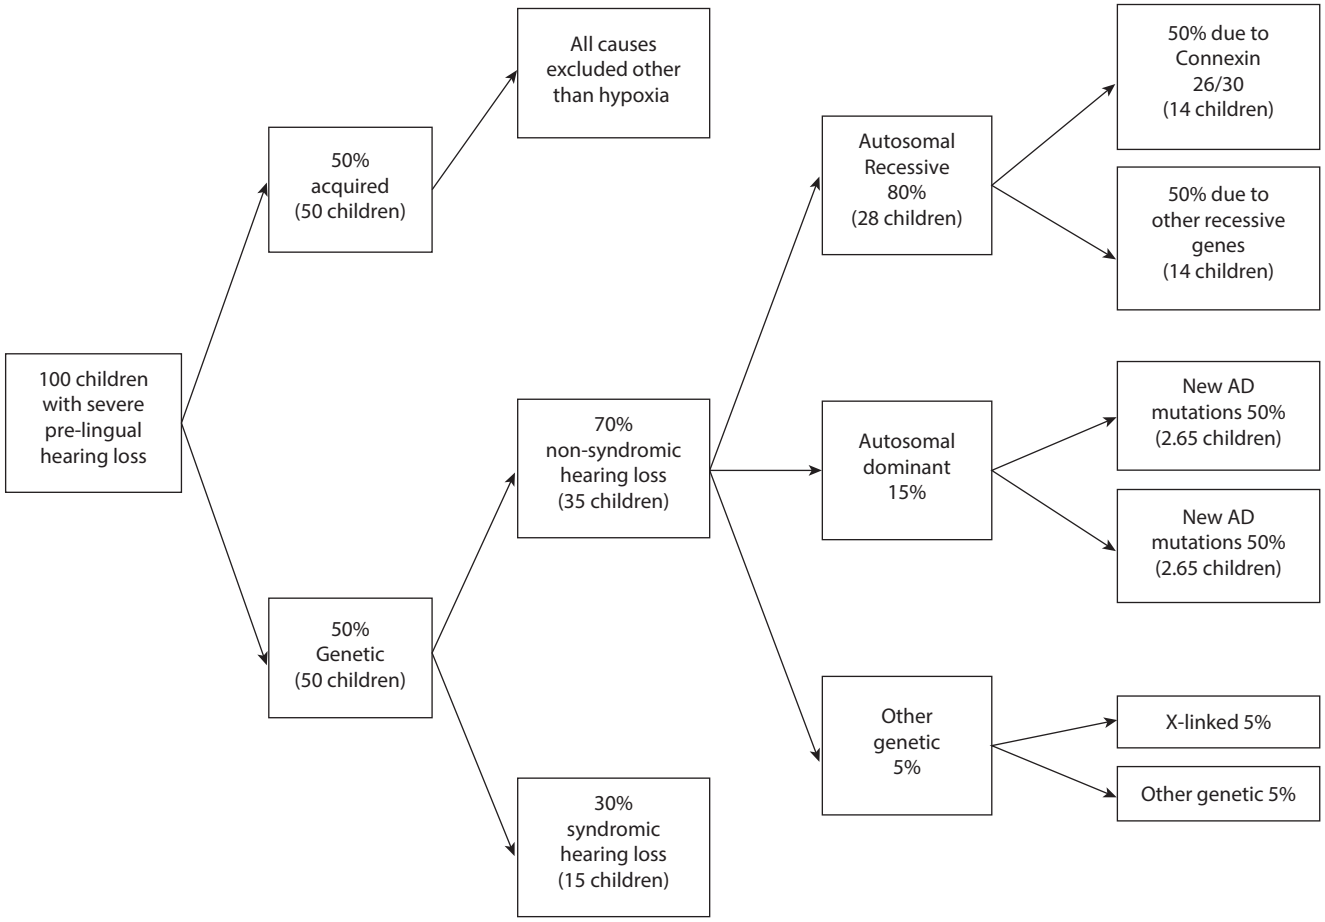

Figure 10.1 Aetiology of hearing loss in children.

rate in the general population for a recessive deafness-causing *GJB2* mutation is about one in 33.[26] Syndromic SNHL is found in conditions such as Pendred syndrome, Branchio-oto-renal syndrome, Usher syndrome and Waardenburg syndrome, amongst others.[19, 20] Conductive hearing loss is commonly encountered in Down syndrome and Treacher Collins syndrome likely to be due to the craniofacial abnormality encountered in these syndromes.

Congenital infection causing hearing loss

Maternal infections are still responsible for a significant proportion of acquired hearing loss, especially in developing countries, although vaccination has greatly reduced the incidence. The distribution of genetic hearing losses are shown in **Figure 10.1**.

Cytomegalovirus (CMV)

Congenital CMV, a herpes virus, is now the most common cause of non-hereditary SNHL in the developed world.[27, 28] CMV infection occurs in about 1% of pregnancies and 40% of affected mothers pass the virus on to the baby. In the UK congenital CMV affects 0.3–0.5% live births, but the incidence varies from 0.2% to 2.2% in other parts of the world.[28–30] Maternal infection within the first trimester is associated with greatest risk.[31] The hearing loss can be of delayed onset giving challenges in predicting which children with congenital CMV infection will develop hearing loss and whether or not the loss will continue to deteriorate.[32] About 30–50% have a unilateral hearing loss that may progress to a bilateral SNHL, so audiological monitoring is important.

Congenital rubella syndrome (CRS)

CRS is probably the most important cause of congenitally acquired hearing loss in countries with no rubella vaccination programme. CRS occurs when there is maternal infection with the rubella virus in the first trimester of pregnancy. It leads to a number of abnormalities in the child including deafness, ocular defects (cataracts, glaucoma), cardiovascular anomalies (patent ductus arteriosus, pulmonary artery stenosis and ventricular septal defects), central nervous system problems (microcephaly, global retardation) and characteristic skin changes (**Figure 10.2**).[33]

The WHO has recommended vaccination against rubella.[34] Two approaches have been suggested: prevention of CRS only, through immunization of adolescent girls and/or women of childbearing age; and elimination of rubella, as well as CRS through universal vaccination

Figure 10.2 Congenital rubella with characteristic skin rash. The child was profoundly deaf. Courtesy of J Verbov, Emeritus Professor of Paediatric Dermatology, Royal Liverpool Children's Hospital, Alder Hey.

of infants and young children.[35, 36] This latter is the norm in most developed countries where CRS deafness is almost unknown.[37]

Syphilis

Syphilis is caused by the bacterium *Treponema pallidum*. It is a common infection in much of the developing world and has recently re-emerged in parts of the developed world. The main route of transmission is sexual contact, but syphilis can also be transmitted from an infected mother to her baby (congenital syphilis). Congenital infection can occur at any stage during pregnancy, but the highest likelihood of damage to the fetus is when infection occurs and is untreated during the first or second trimesters. During primary syphilis, the rate of vertical transmission in untreated women is 70–100%; this drops to 10–40% in the latent stage of the disease. The poorest prognosis is for an infant infected during the first or second trimester by a mother in the primary or secondary stages of disease. Hearing loss is a late feature of congenital syphilis and often appears as one of a group of signs known as 'Hutchinson's triad'. These include inflammation of the cornea giving it an opaque appearance, which leads to loss of vision, peg-shaped upper incisors (Hutchinson's teeth) and VIIIth cranial nerve deafness. Hearing loss is the least common component of Hutchinson's triad and occurs in around 3% of children with late congenital syphilis. It typically appears when the child is 8–10 years of age, although occasionally it may be delayed until adulthood. Onset is sudden and damage to the cranial nerve is thought to result from a persistent and ongoing inflammatory response to the infection. Loss of hearing may be unilateral or bilateral and initially involves higher frequencies, with normal conversational tones affected later.[38] Syphilitic hearing loss is uncommon.[39] Congenital syphilis can be treated with high-dose penicillin, but is best prevented by identification and eradication of the infection in the mother. Pre-natal screening for syphilis is commonplace in developed countries and is the main priority for prevention of the disease in developing countries.[38]

Toxoplasmosis

A systematic review on neonatal toxoplasmosis showed that the use of anti-parasitical therapy initiated early showed very encouraging results in preventing SNHL. Children with congenital toxoplasmosis that had no treatment, partial treatment, delayed onset of treatment, or compliance issues should undergo annual audiological monitoring until able to reliably self-report hearing loss.[40]

ACQUIRED CAUSES

While the frequency of infections has dropped with the introduction of vaccines, a concomitant improvement in the survival rates of pre-term babies has increased the proportion of babies with hearing loss related to perinatal events, including stays in the neonatal intensive care unit (NICU). Pre-term and low-birth-weight infants are particularly susceptible to factors such as hypoxia and hyperbilirubinaemia. Davis and Wood[41] showed that babies admitted to a NICU for more than 48 hours were 10.2 (95%, confidence interval 4.4–23.7) times more likely to have a permanent hearing loss (greater than 50 dBHL in this study) than those who did not undergo intensive care.

Hypoxia is associated with apnoea, difficult delivery, low Apgar scores and use of ventilation. It is known to be associated with neurodevelopmental deficits, but the exact mechanism of hypoxia-related hearing loss is unclear. Although most believe that brain cells are more susceptible to hypoxia than the hair cells in the inner ear, there is some emerging evidence that apoptosis of hearing cells can occur without any injury to brain cells.[42]

Hyperbilirubinemia is an independent risk factor for SNHL in infants. High levels of unconjugated bilirubin have been associated with neuronal damage. The auditory brain nuclei and the inferior colliculi are often the first

part of the brainstem to be involved, often leading to hearing abnormalities.[43] These infants are more often than not nursed on a NICU, where they may receive ototoxic drugs, such as aminoglycoside antibiotics (e.g. gentamicin, tobramycin and amikacin) and diuretics (e.g. furosemide). Aminoglycoside-induced and non-syndromic deafness have been shown to have a genetic susceptibility and the pathogenic mitochondrial 12S rRNA. A1555G mutation was identified as the primary factor underlying the hearing loss in many familial as well as in genetically unrelated cases; also see ototoxicity in acquired causes of hearing loss.[44, 45]

Other causes of permanent acquired hearing loss include bacterial meningitis, chronic otitis media, mumps, measles, trauma, ototoxic drugs and head injury.

Meningitis

The most common cause of acquired PCHI is childhood bacterial meningitis. The risk of developing significant sensorineural impairment after bacterial meningitis has been estimated at approximately 10%.[46–49] but this varies depending on the organism. In the developed world Haemophilus influenza B (HiB) and Meningococcus C (Men C) vaccinations have led to significant reduction in these infections.

All patients should have early audiological assessment after an episode of meningitis. Patients identified with severe to profound loss should be 'fast tracked' for an assessment by a cochlear implant centre to minimize delay as ossification of the cochlear duct can make implantation difficult or even impossible (see Chapter 94, Cochlear implants).

Measles

Measles is a highly infectious viral illness, which presents acutely with high fever, running nose, characteristic Koplik's spots on the buccal mucosa and a distinctive generalized maculopapular rash (**Figure 10.3**). It occurs worldwide but its incidence has reduced significantly in developed countries since the introduction of an effective vaccine in 1968. It is predominantly a disease of infants and young children and occurs mostly after the age of 6 months. Globally, measles is the leading cause of vaccine-preventable child deaths.

Measles has been reported as a major aetiological factor for mild to moderate bilateral hearing loss in deaf children. As it was known that mucous membranes all over the body were affected, the observed hearing loss was previously thought to be conductive and attributable to suppurative otitis media, chronic perforation and mastoiditis, but SNHL occurs as well.

The WHO and United Nations Children's Fund (UNICEF) have emphasized primary prevention of measles in its global campaign against the prevailing childhood illnesses in the developing world for several decades. Immunization for measles can be administered as a single vaccine or as the triple MMR (measles, mumps and rubella) vaccine.

Figure 10.3 Child with maculopapular rash characteristic of measles. Courtesy of J Verbov, Emeritus Professor of Paediatric Dermatology, Royal Liverpool Children's Hospital, Alder Hey.

Mumps

Mumps, caused by infection with the mumps virus, is a non-suppurative enlargement of the salivary glands, particularly the parotids (see Chapter 39, Salivary glands). The infection may be subclinical in up to one third of the cases and in these the first presentation may be the appearance of complications. SNHL as a result of mumps is mostly unilateral and severe to profound, although bilateral loss has been described. The incidence of mumps-related SNHL has been reported as 0.5–5/100,000.[50]

Ototoxicity

'Otoxicity' refers to pharmacological agents that can cause a hearing loss with or without a vestibular loss usually at the cochlear level. The mechanism of action is by their action on the apoptotic pathway of cochleovestibular hair cells where generation of reactive oxygen species is a rate limiting step. The agents implicated are the aminoglycoside group especially gentamicin and tobramycin, chemotherapeutic agents especially the platinum derivatives cisplatin and carboplatin, vinca alkaloids, cyclophosphamide and methotrexate, anti-malarials including chloroquine, diuretics especially frusemide and ethacrynic acid, and iron chelators like desferrioxamine. These agents are not infrequently used in the paediatric population especially in cystic fibrosis, cancers and in paediatric haematological conditions. Chemotherapy ototoxicity monitoring protocols with subjective and objective assessment of hearing and vestibular function is required

to adjust therapeutic dosage. Genetic susceptibilities are reported with both gentamycin and cisplatin ototoxicity.[51]

Autoimmune ear disorders (AIED)

Autoimmune ear disorders can either be primary or secondary. Primary AIED affects only the cochleovestibular apparatus and the hearing loss is non-syndromic with autoantibodies directed only against the inner ear whilst secondary AIED affects multiple organs being part of the wider connective tissue disorder spectrum including rheumatoid and juvenile arthritis, the inflammatory bowel disorder group and for that matter any autoimmunity disorder.[52] The exact prevalence or incidence of AIED in children is unknown. The hallmark of this condition is a sudden SNHL with variable vestibular involvement which is responsive to steroids. Hearing can be salvaged during the acute phase within a critical time frame of 72 hours but in many presentations, this time period may be exceeded leading to a permanent irreversible hearing loss. Diagnosis is still a matter of controversy and inflammatory markers may not be raised especially in primary AIED. Therefore, all children presenting with sudden SNHL should receive a diagnostic and therapeutic steroid administration and a full workup of autoimmune markers.

Third window disorders

A condition involving the bony labyrinth may lead to a mixed hearing loss and can mimic other conditions. These conditions are called third windows and examples include semicircular anal dehiscences, enlarged vestibular aqueducts, X-linked gusher syndromes and dilated internal auditory meati (see Chapter 48, Physiology of hearing). Usually the vestibular system is also affected; therefore, a full vestibular quantification is necessary. In the paediatric population, this is not well researched but is now recognized as a condition which can often be missed.[53]

NEWBORN HEARING SCREENING

It has been shown that early diagnosis of PCHI has an important bearing on outcome. Several studies have demonstrated that children whose hearing losses were identified by 6 months of age demonstrated significantly better receptive and expressive language skills than did children whose hearing losses were identified after the age of 6 months.[54–56]

Prior to introduction of the newborn hearing screen in England and other countries within the UK, infant distraction test (IDT), first used in 1960s, was used as a hearing screening test until early 1990s. It was usually carried out by health visitors at the age of nine months within the community. IDT had neither high sensitivity nor specificity. As a result, a large number of children with normal hearing were referred for further investigations. More worryingly, almost one quarter of children born deaf were not identified until they were over 3.5 years of age.[57, 58] These concerns led to a Health Technology Assessment[59] of hearing screening in England and subsequently setting up of a newborn hearing screening programme (NHSP). As a result of universal neonatal screening in England, the median age of detection of PCHI is now 10 weeks.[60]

Currently, in England, all children are screened with automated otoacoustic emissions (AOAE) as close to the time of birth as possible by a trained operator with over 95% of babies having the hearing screen completed by 4 weeks of birth in hospital hearing screening programmes and within 5 weeks of birth in community newborn hearing screening programmes. AOAE screen is sensitive to hearing losses from 1 to 4 kHz while automated auditory brainstem response (AABR) detects hearing loss in the 2–4 kHz frequencies of more than 40 dBHL. The result of the screen is either a 'pass' or 'refer'. In addition, all NICU babies have AABR screen in addition to AOAE screen. This is because there is a higher incidence of children with permanent hearing loss (including auditory neuropathy, the latter estimated to be 0.9%) whose AOAE test would give a 'pass' result. Normally, a 'well' baby who passes the AOAE screen in both ears would be discharged so anyone in this group with ANSD(see Chapter 69, Auditory neuropathy spectrum disorder and retrocochlear disorders in adults and children) will be missed at this stage. Fortunately only 5–7% of all ANSD patients come from the 'well baby' population. On the other hand babies from NICU will have both AOAE and AABR screening tests and therefore anyone with a moderate or greater cochlear or neural hearing loss (up to the brainstem) should be identified by the NICU screen protocol.

In some babies the hearing loss could be progressive, and may develop after birth. As passing a hearing screen at or soon after birth can give a false sense of security to parents and professionals alike, it is extremely important to be vigilant so that any future suspicion of hearing loss is investigated promptly. In most countries there is some form of targeted follow-up of the babies with a risk factor, who passed the neonatal hearing screen.

More information on screening can be found in Chapter 8, Hearing screening and surveillance.

Unilateral hearing loss (single-sided deafness)

Screening has also resulted in early detection of unilateral permanent hearing loss. In the past, unilateral hearing loss (UHL) was considered to have little impact on speech and language development; this is not the case.[61] The yield for permanent unilateral moderate or greater hearing loss in the NHSP in England is 0.64 (95%, CI 0.37–0.91) per 1000 screened.[60] UHL can also be acquired as a result of trauma, infection, ototoxicity, metabolic disorders and surgery. UHL results in an inability to hear binaurally (from both sides), leading to difficulty in hearing speech in noise and poor localization of sound. Further, with frequent middle ear infections or effusions in the early years, those with a UHL may be at a greater risk of suffering with periods of significant hearing difficulties. School children with UHL may have increased rates of grade failures, need additional educational assistance and may

show behavioural issues in the classroom.[61] A unilateral conductive loss arising from atresia (absence of the external ear canal) has also been shown to have an impact on academic performance.[62]

It is unclear if children always 'catch up' as they grow older.[61, 63]The impact of UHL on language development and educational performance varies considerably but it needs to be kept in mind.[64] It is important to assess these children on an individual basis and make available appropriate support if needed, but many children can be managed expectantly.

Current practice is that UHL is investigated to identify progressive pathology or conditions that might affect the other ear, e.g. dilated vestibular aqueducts. Audiological management of children with UHL includes regular monitoring of their educational performance and maintenance of their technology by their teachers supported by specialist advisory teachers of the deaf (ToD), and environmental modifications including minimizing background noise and reverberation in the classroom and preferential seating nearer the teacher. More recently an increasing number of children with UHL have been fitted with and benefited from various hearing devices including contralateral routing of signal (CROS) hearing aids, bone conducting hearing implants (BCHI)) and FM devices such as iSense (see Chapter 93, Bone conduction hearing aids).[64–67]

Progressive hearing loss

Some children have normal hearing or only a mild loss at birth, but develop progressive hearing loss with time. Prevalence of permanent SNHL almost doubles by the second decade of life.[17] This group includes those with progressive as well as post-natally acquired hearing loss, highlighting the importance of continuing vigilance.

In countries where universal neonatal hearing screening has not yet been established, identification of children with PCHI is still dependent on parental or teacher suspicion, locally arranged behavioural screening programmes or questionnaires and preschool screening. In a questionnaire-based study in Nigeria, only 12% of parents of a child with hearing loss suspected hearing difficulty by the age of 6 months. Parental suspicion occurred mostly at 12–24 months, compared with 8–14 months in developed countries. The most common mode of detection was a child's failure to respond to sound (49%).[68] Since this study Nigeria has started a newborn hearing screening programme leading to early detection of hearing loss in that country.[69]

Progressive hearing loss may be due to genetic or environmental causes. In some syndromes such as Pendred syndrome, the hearing loss is typically progressive. Non-syndromic hearing loss related to a variety of known and unknown mutations can also be fluctuant or progressive.[70] Some infections such as congenital CMV and occasionally congenital syphilis can cause late-onset or progressive hearing loss. Similarly, children who contract bacterial meningitis, viral infections such as mumps and measles, chronic otitis media, suffer trauma including noise exposure or ototoxicity (e.g. aminoglycosides, platinum drugs) require audiological assessments. Early detection of hearing loss in these groups is based upon surveillance of at-risk groups (e.g. children undergoing chemotherapy) and parent/teacher/medical staff suspicion.

This group poses a challenge, as neonatal screening will not identify them and school entry screening no longer takes place in the UK. Identification of these cases therefore is dependent upon a high degree of suspicion in children with known associated syndromes, careful surveillance and prompt assessment in response to parent or teacher concern regarding hearing or speech and language development.

THE NEWLY DIAGNOSED DEAF CHILD AND FAMILY

For the majority of parents, having a child with hearing loss is completely unexpected; about 95% of deaf babies are born to hearing families.[71]

Parents remember with clarity the day they were told their baby was deaf, and cumbersome inexpert handling of this scenario can have profound adverse long-term effects. An experienced empathic team that works in a coordinated way with the family and can present a knowledgeable and non-partisan approach to the various options and resources available makes for the best outcome for parents and child. Now the diagnosis is likely to take place very early in the child's life while parents are adjusting to being parents and it is even more important that time is made available for them and that they are supported in the early days.

Parents may experience a range of emotions following diagnosis of hearing loss, including shock, confusion, depression, anger and guilt.[72] The presence of a child with hearing loss has often been linked with psychosocial stress in the parents and other family members,[73] but better information regarding screening and rehabilitation help families to deal with the trauma. The degree of hearing loss does not seem to influence the parents' reactions. In fact, stress levels were found to be higher in the parents of children with less severe hearing loss.[74] This might be because the child with a less severe hearing loss may at least sometimes respond to some sounds, which can delay the parents' adjustment to the hearing loss and confuse the diagnosis. Parents and healthcare professionals are faced with a series of dilemmas and challenges when it is established that a child is deaf. Parents will have questions regarding the reason for the hearing loss, prospects for development of the child – especially speech and future communication – and educational needs. Many of these questions cannot be answered straight away but parents are often required to make decisions without having time to take in the information they have been given before they have been able to adjust to having a child with hearing loss. Ensuring that parents and child develop effective early communication skills is vital to support language development.

The impact of the diagnosis on parents and family can remain in the long term when the further implications on education, social life and self-esteem become apparent. It is therefore vital that the process of screening and diagnosis is carried out by experienced multi-professional teams and that parents and family have continuing support.

Meeting other families has been found to be useful and the National Deaf Children's Society[9] provides helpful services and resources, as does SoundSpace.[75]

Medical management

While appropriate and optimum amplification along with early support is essential to achieve the best audiological outcome, deafness is a symptom rather than a definitive diagnosis, and it is important to identify the underlying cause and associated conditions, if any, as these may need their own management. A holistic approach often leads to better overall outcomes. for the child and family.

Medical management consists of a developmental assessment and identifying coexisting medical conditions as well as carrying out an extensive investigation into finding the cause of the deafness. It is therefore essential for every audiology team to have an appropriately trained medical practitioner, preferably at consultant level, to provide this aspect of care and support for children diagnosed with a hearing loss, and for their families. Investigating aetiology is an important and integral part of the management of a child with hearing loss at any age primarily to answer two questions:

1. How might the hearing loss evolve? This, in turn, alleviates uncertainty.
2. Is there a genetic factor for patients and parents/carers? They can be counselled from a genetic point of view.

In the UK, national guidelines for investigating the aetiology of PCHI were developed by the British Association of Audiological Physicians[2] in conjunction with the British Association of Paediatricians in Audiology[1] and are available on those two websites. It is recommended that core investigations are offered to the parents of all children with a newly diagnosed SNHL, while 'additional' investigations are dictated by individual circumstances and the findings of core investigations (Table 10.2). Parents may not wish to pursue investigations at such an early stage, the results of which in many cases may have no immediate impact on the management of the child and the family, but it is essential that healthcare professionals are aware of the baseline investigations and can discuss the rationale behind various tests so parents can make an informed choice.[2] These guidelines are not always fully implemented.

The aims of aetiological investigations are:

- to try to provide reasons for the deafness for parents
- to identify conditions that may affect audiological and medical management
- to provide better advice to parents with regard to best management of associated conditions
- to assist the family in making educational and management decisions for the child
- to inform genetic counselling
- to inform epidemiological research.

The recommendation is that patients should undergo core investigations with additional investigations as dictated by the clinical scenario.

History

A detailed and careful history of the pregnancy, perinatal period and birth and the post-natal period including

TABLE 10.2 Core investigations for all cases of bilateral severe to profound sensorineural hearing loss

Investigation	
Paediatric history	Detailed history of pregnancy delivery and postnatal period. Developmental milestones including speech and language and motor milestones, pre- and postnatal noise exposure, history of ototoxic medications, head injuries, ear disease, meningitis, viral illness and immunization status
Family history	Deafness or risk factors associated with hearing loss in first- and second-degree relatives
Clinical examination	Inspection and physical measurement of craniofacial region, assessment of the neck, skin and nails, limbs, chest and abdomen. Developmental examination
Audiology	Age-appropriate assessment including tympanometry. Audiometry on first-degree relatives
Imaging	Magnetic resonance imaging of inner ears and/or computed tomography of petrous temporal bones.
Electrocardiograph	
Urine for microscopic haematuria and for CMV DNA PCR in neonatal congenital hearing losses	
Connexin 26 and 30 mutations testing with access to clinical genetics service for counselling	
Ophthalmic assessment	
Referral to clinical geneticist	
Vestibular investigations	
CMV serology	

infections and medication is invaluable. Wherever possible, maternity and birth-related notes should be examined. Note details of drugs used, if appropriate with doses, duration and the blood levels of any potentiating medication. If jaundiced, blood levels of unconjugated bilirubin levels and the baby's condition at the time e.g. acidosis etc. should be noted. A history of hypoxia should be explored in great detail including length of ventilation, blood gases, metabolic evidence of hypoxia and evidence of any other neurological effects including memory and learning difficulties. It is important to note that, although hypoxia alone does not cause isolated sensorineural loss, there is recent evidence that cochlear cell death can occur without evidence of hypoxic brain injury.[42] Family history of hearing loss, speech and language delay and medical conditions should be explored.

Clinical examination

All children with hearing loss of unknown cause should be evaluated for features associated with syndromic deafness. Important features include branchial cysts, sinuses, fistulae and pits, pre-auricular appendages and pits, telecanthus, heterochromia iridis, white forelock, pigmentary anomalies, high myopia, pigmentary retinopathy, goitre and other craniofacial anomalies, palatal abnormalities e.g. cleft palate, submucus cleft, high-arched palate and abnormalities of teeth etc. It is also useful to look for any dysmorphism in the immediate family.

Audiology

Skilled audiological testing must be performed to assess the severity of the hearing loss and to determine whether it is conductive, sensorineural or mixed. This is discussed in detail in Chapter 9, Hearing tests in children. This should include ear specific hearing thresholds with ear and bone conduction as appropriate and testing for neural involvement e.g. ANSD where appropriate as per NHSP) protocols.[76, 77]

Imaging

The aetiology of profound hearing loss in children is multifactorial. Cross-sectional imaging is extremely useful in the detection and management of congenital abnormalities. Generally computed tomography (CT) including 3D reconstruction would be useful for exploring conductive hearing losses, inner ear bony dysplasia and large vestibular aqueduct syndrome. It is also of use to define facial nerve anatomy, integrity of the ossicular chain and dimensions of the internal auditory canal. MRI scans are more likely to detect abnormalities primarily involving the membranous labyrinth, and lesions of the central auditory pathway in the internal auditory canal, cerebellopontine angle, brainstem and cerebral cortex.[78–80] Bamiou et al. reported that about 28% of children with profound and/or progressive hearing loss and/or craniofacial abnormalities have an abnormal CT scan whereas, the child's gender, consanguineous parents, or family history of SNHL were far less likely to be associated with CT abnormalities.[81]

Dilated vestibular aqueduct was significantly correlated with the presence of progressive SNHL. At least 40% of children with large vestibular aqueduct (LVA) will develop profound SNHL. An interesting meta-analysis by Spencer et al.[82] reported on the linear relationship of hearing loss to LVA duct diameter. The identification of LVA should raise the suspicion of Pendred syndrome and thyroid abnormality but it also occurs in Branchio-oto-renal syndrome (BOR).[19, 20, 83] Patients with LVA are at risk of progressive deafness after minor head trauma. Identifying this anomaly influences management as it prompts a search for treatable thyroid function anomalies and parents can be counselled with respect to the dangers of incidental head trauma.[73]

Imaging can highlight characteristics of congenital syndromes such as BOR, CHARGE, X-linked and Waardenburg syndromes. In later life, inner ear infections, inflammatory conditions, trauma and tumours come to the fore.[8]

Studies of unilateral SNHL strongly support the need for imaging. Abnormalities on CT imaging have been detected in between 28% and 66% of sequential observations (**Figure 10.4**). There is a slightly higher yield of radiological abnormalities with increasing severity of hearing loss and a significantly higher imaging yield with unilateral than with bilateral SNHL.[81, 85–87]

Imaging modalities and techniques are discussed in Volume 1, Chapter 57, Imaging in head and neck endocrine disease and Volume 2, Chapter 97, Imaging of the temporal bone.

Blood tests

Although routine blood tests such as full blood count (FBC), thyroid function tests, erythrocyte sedimentation rate (ESR), syphilitic blood tests, cholesterol and triglyceride levels, urea and electrolytes are carried out, abnormalities are rarely related to the cause of the hearing loss.[85] The use of these blood tests is dependent on clinical suspicion of various conditions although some tests may be used as generalized screening tests e.g. inflammatory markers. **Table 10.3** lists these tests.

URINALYSIS

Simple testing for proteinuria and haematuria can identify renal disease and can be found in Alport syndrome.

TABLE 10.3 Additional investigations

Investigations
Haematological and biochemical tests
Serological test for congenital rubella and other infections e.g. syphilis, toxoplasma etc.
Thyroid tests
Immunology tests
Metabolic screen blood and urinalysis
Renal ultrasound
Chromosomal analysis

Axial high resolution CT scan through **(a)** dilated vestibular aqueducts and **(b)** a more inferior slice that shows bilateral dysplastic vestibules. **(c)** Coronal image through the abnormal cochlea showing typical Mondini abnormality with incomplete formation of the apical and middle turns of the cochlea. Images kindly supplied by D Saunders, Consultant Neuroradiologist, Great Ormond Street Hospital, London, UK.

SEROLOGY

Universal neonatal screening will detect less than half of all SNHL caused by congenital CMV infection[88] as the hearing loss in a large proportion of children with congenital CMV is progressive.[89] Laboratory testing has to be carried out in neonatal samples within 3 weeks of life for diagnosing congenital CMV. This presents difficulties as after 3 weeks of age, virus isolation could be due to acquired infection, which is not usually associated with adverse outcomes although there are a few publications suggesting extremely pre-term and immunocompromised babies can be susceptible to hearing loss from post-natally acquired CMV.[90, 91] Previous studies[28, 92, 93] have shown that dried blood spots on Guthrie cards collected at birth for the screening of metabolic disorders have proved a valuable tool for retrospective demonstration of CMV DNA for diagnosing congenital infection after months or even years of life. However, as the sensitivity of this test in symptomatic babies is around 90%, absence of CMV DNA in the dried blood spot does not necessarily exclude congenital infection. Infants who are born to sero-immune mothers are not completely protected from SNHL, although their hearing loss is often milder than that seen in CMV-infected infants following primary maternal infections. Late-onset and progressive hearing losses occur following congenital CMV infection and CMV-infected infants should be evaluated regularly to provide for early detection of hearing loss and appropriate intervention. Fluctuating hearing loss that is not explained by concurrent middle ear infections is another characteristic of CMV-related hearing loss in children.[32] Consideration for targeted screening and appropriate early treatment to reduce long-term morbidity is a potential option.[94, 95]

Rubella-specific IgG and IgM synthesized by the fetus are detectable at birth in CRS. However, since maternally derived rubella-specific IgG is also present in infants' sera, laboratory diagnosis of CRS is almost invariably made by detection of rubella-specific IgM responses. This response is detectable in almost 100% of CRS cases up to age 3 months with the most sensitive antibody-capture assays. The response declines progressively to less than 50% at 12 months and is rarely detectable after 18 months. It is therefore suggested that there is value in testing for CRS only if the deafness is identified within the first 6 months of life.[96]

OPHTHALMOLOGICAL ASSESSMENT

A comprehensive ophthalmic assessment is required as deaf children are heavily reliant on the sense of vision in order to develop efficient communication skills and explore the world around them. Any ophthalmic disorder needs to be recognized as soon as possible to optimize language development (spoken or sign, or both). These disorders may be correctable (such as myopia) or treatable (such as cataract). Those children with non-correctable and non-treatable visual disorders, like retinitis pigmentosa in Usher syndrome, require multiple environmental adaptations and appropriate support services and information.[97]

ELECTROCARDIOGRAM (ECG)

Deafness and electrocardiographic changes (prolongation of the Q-T interval and inversion of the T wave) with a clinical picture of syncopal attacks and sudden death, were described as a distinct syndrome by Jervell and Lange-Nielsen in 1957.[98] The syndrome is inherited as an autosomal recessive trait. This syndrome should be sought in children with syncope or a family history of it, especially those with congenital deafness.[99] Cardiologic control is required. The auditory and language outcomes after cochlear implantation in this syndrome are no worse than those in patients with non-syndromic sensorineural deafness.[100]

GENETIC SCREENING

The disorder DFNB1, caused by mutations in the *GJB2* gene (which encodes the protein connexin 26) and the *GJB6* gene (which encodes the protein connexin 30), accounts for about 50% of ARNSHL. The carrier rate in the general population for a recessive deafness-causing *GJB2* mutation is about one in 33 although this can vary according to racial background.[101] It is current practice

that the families of all children with bilateral PCHI are offered genetic screening for these two mutations. Establishing a molecular diagnosis of *GJB2*-related deafness is important clinically since these children can avoid some of the other aetiological investigations (although it must be remembered that dual pathology could exist) and usually are not at increased risk for medical comorbidity. In general, bony abnormalities of the cochlea are not part of the deafness phenotype and developmental motor milestones and vestibular function are normal.[102] The hearing loss associated with *GJB2*-related deafness can vary from mild to profound although most have a symmetrical severe to profound SNHL.[103] The diagnostic yield of *GJB2* screening is significantly higher in patients with severe to profound SNHL than in all other groups.[85]

There have been significant developments in genetic screening. Screening for the mitochondrial gene mutation *A1555G* (that makes individuals susceptible to aminoglycoside ototoxicity) is offered to patients who have developed hearing loss following exposure or to those individuals who are more likely to have repeated exposure to such antibiotics. If the gene is identified and subsequent administration of aminoglycosides restricted, then the severity of aminoglycoside-induced hearing loss can be limited. Also, as the gene is inherited from the mother, genetic screening to those members of the family and also restricting the use of aminoglycosides in maternal relatives will also limit the likelihood of hearing loss caused by these drugs. Hereditary Hearing loss[5] aims to give an up-to-date overview of the genetics of hereditary hearing impairment for researchers and clinicians working in the field.

SUPPORT AND EDUCATION

With the introduction of newborn hearing screening, the development of more effective hearing technologies including digital aids, implantable devices and wireless technology, and greater understanding of the implications of hearing loss on the development of communication, language and cognition, the opportunities and expectations for deaf children have changed dramatically. New communication technologies such as remote captioning, Skype and Facetime enable deaf young people to be supported in education in new ways. This has had great implications for all those involved with deaf infants, children and young people and their families, including audiologists, medical practitioners, speech and language therapists, teachers of the deaf and educational psychologists.

Early intervention

Following the introduction of newborn hearing screening, and the routine fitting of hearing aids in the first few months of life, and implantable devices in the first year of life, speech and language therapists and teachers of the deaf are involved with deaf infants and their families providing early intervention services at a very early stage. At this time the family may be faced with coming to terms with the diagnosis and new terminology and technology, while dealing with a young baby in their family. The consensus statement for Family Centred Early Intervention[104] provides useful guidelines, recommending the provision of:

- early timely and equitable intervention
- family provider partnerships
- informed choice and decision making
- family, social and emotional support
- family infant interaction
- use of assistive technology and supporting means of communication
- qualified providers
- collaborative teamwork
- progress monitoring
- programme monitoring

They provide guidance under each section and helpful resources, with the emphasis on family-centred services. These requirements place a great responsibility on the team providing the early intervention, particularly as we know its effectiveness has a positive long-term impact on outcomes in terms of language and education for the deaf infant. Early intervention is a strong predictor of later outcomes.[105, 106]

Hearing technology

See Chapters 54, Hearing aids, 55, Beyond hearing aids: An overview of audiological rehabilitation, 93, Bone-conduction hearing aids and 94, Cochlear implants for a comprehensive description of the rapidly changing available technology. Interventions include digital hearing aids, implantable devices (cochlear implants, bone-conduction hearing implants on softband for young children, middle ear implants), and assistive technologies such as FM systems and wireless technology.

The earlier that hearing aids or implantable devices are provided for a deaf child, the more effective they are known to be in the long term.[106] The early intervention team is key to their acceptance and use on a daily basis. For the family of a young deaf infant, adapting to the use of this technology can be challenging when coming to terms with the diagnosis and the implications of hearing loss. The technology itself may be complex to deal with in a family setting with a young baby and it is important that the audiology service liaises closely with those working with the family to ensure that there is a shared understanding of the implications of the hearing loss and expectations of the technology. The technology is changing constantly including sophisticated programmable hearing aids, electro-acoustic implants for those with high-frequency losses, middle ear and brainstem implants and developing techniques. Much information is available on websites and it is essential that all in a position of advising families keep up to date with current practice. Meeting other families and young people using the technology is helpful, and useful resources, including DVDs, are available from www.ndcs.org.uk[9] and from www.earfoundation.org.uk.[107]

The education of deaf children

The impact of childhood hearing loss on communication and language development and hence on educational outcomes and educational decisions has long been recognized as significant, and how to overcome it the source of much controversy with little in the way of evidence.[108] The seminal work of Conrad[109] showed that half of deaf children leaving school had speech that was 'difficult to understand' and had a median reading age of 9 years. Little changed with regard to educational outcomes until comparatively recently. With the rapid growth of hearing technologies, their earlier use, and more sophisticated assistive devices to address the problems of listening in noise and over distance, the impact of hearing loss on language and education has changed considerably in recent years.

Deaf children and young people represent challenges for researchers: they are a particularly heterogenous population with many variables to account for, including aetiology, age at diagnosis and amplification, cognitive ability, socioeconomic status, parental support, communication preference and educational management. Cochlear implantation has added more variables, including device used, age at implantation, surgical technique, generation of device and programming strategy. The impact of profound deafness on communication is readily apparent, but even a mild or moderate, or unilateral hearing loss which may not be so apparent can have an educational impact, with delayed language and a disadvantage in the classroom.[61, 110–113] A mild—moderate hearing loss impacts on the development of language and reading skills and hearing in one ear makes listening in noise and the localization of sound challenging, impacting on the ability to participate in the classroom.[113] A conductive, long-lasting hearing loss can also have a significant impact on access to the curriculum in the classroom; its fluctuating nature can exacerbate the difficulties it causes in listening in the classroom. In spite of this, the impact is often not recognized or addressed: for example, only 68% of deaf educational services are reported to support children with a conductive loss.[112]

Early identification, followed by early amplification has been shown to improve auditory abilities and hence language outcomes,[115] and the comprehensive LOCHI (Long-term outcomes from childhood hearing impairment) in Australia has demonstrated the benefits of early amplification.[116] The study showed that early intervention, maternal education, the absence of additional difficulties and oral communication in early intervention were linked to higher language scores. Early cochlear implantation has long been shown to be a predictor in producing language growth comparable to hearing peers[116–118] and is linked to improved spoken language acquisition, speech intelligibility, educational outcomes and greater participation in mainstream education.[119, 120]

More recent studies of educational outcomes show the positive impact of early cochlear implantation on educational outcomes including literacy; the study of Mayer et al.[121] found that of 33 young people aged 9–16, 75% were within the normal range for reading comprehension, when compared with hearing peers. Mayer and Trezek[122] reviewed the literacy outcomes for deaf students with cochlear implants with encouraging results.

However the picture remains complex. The National Deaf Children's Society, commenting on the Department of Education's report on children's grade attainment in 2015, pointed out that in spite of an increase in the numbers of deaf children achieving five GCSEs (41.1%), almost two thirds (58.9%) were failing to achieve the government's expected benchmark of five GCSEs at grade A*–C (including English and Maths), compared to just 35.8% of other children with no identified special educational need (from www.ndcs.org.uk).[9]

In spite of the progress made following early detection and intervention, hearing loss still has an educational impact. It impacts negatively on the more subtle areas of language development such as pragmatic skills.[105, 123, 124] Together with challenges in acquiring world knowledge, there remain challenges for deaf children in some higher order reading skills, such as inferencing skills, impacting on later educational attainments.

Schools and language teaching

Specialist education for deaf children was established long ago, with large schools for deaf children in many countries in the latter half of the nineteenth century and children taught according to the prevailing philosophy in the school, whether orally or using sign language. During the second half of the twentieth century more deaf children were educated in integrated settings, with their hearing peers, supported by improved technology, such as the fitting of FM systems which enabled teachers to use a microphone to aid communication with the deaf child (**Figure 10.5**) (Chapter 54, Hearing aids) and overcome the issues of background noise and distance, coupled with the political will to include more children with disabilities in mainstream education. Now the terms 'inclusive education' and 'least restrictive environment' are used internationally and supported by the legal requirement in most developed countries for deaf children to have an individual education programme with their needs identified.

Figure 10.5 A teacher of the deaf using an FM microphone.

More information on the history of deaf education can be found at www.batod.org.uk.[10]

Children with hearing loss may be educated in mainstream schools with or without support, in a special class or resource base in a mainstream school, in a specialist school for the deaf, or in a school which specializes in children with other difficulties, such as visual impairment, or language difficulties. The majority of deaf children are now in mainstream schools, where there may be challenges for access to the expertise and management necessary to overcome the impact of deafness and to fully utilize the technological and communication support available today.

The comprehensive CRIDE (Collaboration for Research in Deaf Education) 2015 report for the UK, available from www.batod.org.uk)[125] reveals that:

- 65% of deaf children are in mainstream provision
- 6% are in resource bases in mainstream
- 2% are in schools for the deaf
- 10% are in other special schools
- 15% are educated at home.

Whether to use a signed or oral approach has long been contentious. The Milan conference of 1880 concluded that the deaf were to be taught by oral means with the 'uncontestable superiority of speech over sign' and thus began 100 years of the dominance of oral education over sign – at a time when useful hearing could not be provided. The 'oral' view was challenged strongly by the reports of poor linguistic and educational outcomes[125] and by the increasing voice of the deaf community, promoting its own culture and language. Sign language is silent, with a grammar of its own and cannot be used with spoken language, and an interest in sign bilingual programmes where sign language is used independently of spoken language grew. To summarize, communication choices used with deaf children can be categorized in three major groups:

- oral/aural alone;
- those approaches using speech and sign (total or simultaneous communication);
- sign bilingualism.

There is increasing evidence that the new technologies of implantation and of earlier identification are changing some of these educational decisions.[126] There appears to be an increasing percentage of deaf children in the UK using spoken language. The CRIDE[125] shows that 87% of deaf children use spoken English or Welsh, with 2% using British or Welsh Sign Language and 8% using spoken English with signed support. The lack of empirical evidence for sign bilingualism and the better outcomes in terms of spoken language from early diagnosis and cochlear implantation than were predicted have been recognized.[126] While the evidence for the best method to support the development of improved educational outcomes remains contentious, an oral input, rather than a sign bilingual one, is most effective in producing spoken language outcomes.[116, 129] This may be provided with signed support for spoken language, for those who may need some visual support, either prior to implantation or in specific situations.[130]

Whatever the educational placement of the child it is important to ensure that the child's educational and social needs are met. Medical and audiological services have the goal of improving hearing and general health; for the educator there may be differing goals – those of literacy and numeracy and of social and emotional wellbeing. With regard to social and emotional wellbeing, there is no evidence to show that the advent of cochlear implantation has had an adverse effect on young people's wellbeing. Several studies show that young people with implants have a flexible view of their identity, as being both deaf and hearing, and have mental health status on a par with their hearing peers[131] and most do not relate to deaf culture as in the past.[132]

With the huge impact of today's technology on educational outcomes and management by providing useful hearing from an early age, it is vital that the technology supporting the child's access to the curriculum is used effectively; the acoustics in schools are often poor, the technology can be difficult to manage, particularly in a mainstream setting, and there may be considerable discrepancy between the child's functioning in the clinic and in school. Much of classroom learning takes place in group settings, which can be challenging for hearing aid or implant users, and the problem of signal to noise ratio (SNR) can be difficult to overcome. The acoustics of the educational setting need careful consideration, and a clinician involved in the fitting of hearing aids or implants should ensure that the child's teacher or classroom assistant understands the technology, can carry out simple trouble-shooting and has access to spares to ensure that the child is not without their amplification during the day. Accessories such as radio hearing aid systems (or FM), or the developing wireless, streaming systems or sound field systems are increasingly common, but need to be managed in the classroom rather than in the clinic. Children and young people are unlikely to use their equipment if it is not functioning properly, and the growing complexity of the technology demands increasing competence from teachers and increasing liaison with the audiology clinic. Communication technology is increasing in effectiveness too — remote captioning on tablets is available for use in school, college and work, and communication systems such as Skype and Facetime make lectures and meetings more widely accessible to deaf children and young people.

An additional challenge for deaf education in today's technological era is the growing number of deaf children with additional difficulties, and often very complex needs. CRIDE[125] reports that 21% of deaf children have an additional difficulty. Vestibular dysfunction is also very common in this group of children, and often overlooked. For these children it is even more important to ensure that today's audiological and communication technologies are available. It has been shown that they may not be referred for cochlear implantation in a timely fashion[133, 134] and parents reveal that education and the management of

audiology technology in schools which are not specialist schools for the deaf is a particular issue.[133] These are children for whom access to hearing can be particularly important, although the outcomes may not include the acquisition of spoken language and ones who present challenges for cochlear implant teams.[134]

Educational services for deaf children have a particular responsibility in times of challenging financial constraints and also of developing and changing technologies to ensure that children are monitored for changing hearing needs. For example, those with progressive hearing loss, and those for whom their hearing aids may not be sufficient and who should be referred for cochlear implant or bone-conduction hearing system. This responsibility involves training mainstream teachers in the monitoring of children and young people in the classroom and providing them with information about what changes in behaviour may be significant and where and how referrals should be made.

Support into further education and the world of work

Teachers of the deaf are now responsible for young people with hearing loss until the age of 25, and therefore now working in further and higher education settings and supporting young people into the workplace. The transition to further education and into the workplace is challenging, but it is essential that support is continued there and that young people learn to advocate for themselves and ensure whatever communication and hearing technology they require.

A report by Ng[135] revealed that these young adults have little or no communication or technology support as they enter work, and little knowledge of what is available to them. The continued positive impact of early diagnosis, intervention and today's technology require support into adulthood, to ensure long-term benefit.

Worldwide, the role of the teacher of the deaf is being challenged in these changing times. Teachers are likely to be involved with deaf children early in infancy and with their families, and require quite a discrete set of skills to effectively support parents and child at this vital time. With today's technologies, the educational needs of deaf children and young people are more subtle than they were previously, when they were more obvious. Teachers of the deaf work in a greater range of educational settings, with a greater range of deaf children than before, at a time where services are financially challenged. New ways of working enable education and audiology to be linked efficiently via Skype sessions, with the programming of cochlear implant systems in schools, and data logging on hearing aids and implants providing information to the clinic about what is happening in everyday life. There is a greater than ever need for collaboration between education and ENT and audiology departments to ensure that the benefits of today's technologies can be realized in education.

BEST CLINICAL PRACTICE

- ✓ All children with PCHI should have a full history and clinical examination, with audiological testing as appropriate to the child's age. Families should be offered aetiologiocal investigations to include imaging, genetic testing and other investigations as per published guidelines, followed by appropriate management of associated conditions and skilled genetic counselling.
- ✓ Optimum initial management is with early fitting of binaural hearing aids.
- ✓ If hearing aids are not appropriate early referral should be made for assessmnt of otological implants including cochlear implantation.
- ✓ Clinicians involved in the fitting of hearing aids or implants should ensure that the child's teacher of the deaf understands the technology, can carry out simple trouble-shooting and has access to spares to ensure that the child is not without their amplification during the day.
- ✓ Although the optimum management strategy for single-sided deafness is unknown, the child's teachers should be made aware of this condition.

FUTURE RESEARCH

- ➤ Vaccination programmes, particularly for measles and rubella, will have an important influence on reducing the incidence of PCHI in the developing world.
- ➤ Hearing aid technology continues to improve. These technological improvements need to be accompanied by wider worldwide distribution and availability of hearing aids.
- ➤ Establishing techniques for making a precise diagnosis in genetic deafness, with research into analysis of identified genetic abnormalities to inform focused genetic counselling and may ultimately facilitate therapeutic interventions.
- ➤ Imaging techniques continue to improve and are helping to facilitate more precise anatomical diagnosis.
- ➤ There is a need for further population studies on the effect of single-sided deafness and for a rational approach to management and surveillance for these children.
- ➤ Implementation of the 2016 WHO resolution[136] by governments and international public health legislators would greatly improve detection, prevention and treatment of childhood hearing loss.

KEY POINTS

- One infant per thousand is born with permanent deafness or hearing impairment that significantly affects language and social development. a further one per 1000 develops permanent deafness during childhood.
- Early identification and habilitation and optimal audiological and medical management leads to better life chances for the child.
- The benefits of universal screening are now widely accepted as best practice.
- Approximately half of permanent childhood hearing impairment is caused by genetic factors.
- Neonatal screening programmes have brought about earlier diagnosis, but some children with progressive hearing loss will not be detected unless surveillance is carried out during childhood.
- Unilateral hearing loss is detected much earlier as a result of universal screening.
- There is better understanding of optimum management of unilateral hearing loss to include active classroom management and amplification.
- Improved imaging and advances in genetic testing have meant that a precise aetiological diagnosis can be made in an increasing proportion of deaf children.
- A diagnosis of deafness has profound psychological and social implications for both the parents and the child.
- Patients who have had meningitis should have early audiology assessment.
- Initial management is usually with hearing aids but early referral for otological implants should be considered.
- Educational support is an essential part of the management of a deaf child and his/her family.
- Liaison between audiology and educational services is vital to ensure the technology is fully utilized in school.

CHAPTER 11

PAEDIATRIC IMPLANTATION OTOLOGY

James Ramsden and Payal Mukherjee

SEARCH STRATEGY

Data in this chapter may be updated by a PubMed search using the keywords: paediatric, cochlear implant, middle ear implant, auditory brainstem implant, bone conducting implant, BAHA and focusing on diagnosis, surgery and management. The evidence in this chapter is mainly levels 3/4. The clinical recommendations are predominantly B and C.

INTRODUCTION

Paediatric hearing implants have become a routine part of the rehabilitation of deaf children. Cochlear implantation is one of the most dramatic and life-changing medical innovations of the 20th century. Bone-conducting hearing aids are an important tool for restoring hearing to deaf children if conventional hearing aids are ineffective, and middle ear implants are now starting to be used in specific indications in children. Developments in the field are driven by three main forces: technological progress, greater surgical confidence, and psychophysiological understanding of early language development. This chapter reviews the current boundaries for the clinical use of auditory stimulators to establish hearing in deaf children.

The auditory rehabilitation of prelingually deaf children has been revolutionized by cochlear implantation.[1] To date, more than 150 000 children have received cochlear implants, with often spectacular results. Cochlear implants provide access to sound that enables development of speech, language and literacy as well as attendance in mainstream education for many deaf children and is established as an effective and cost-effective intervention.[2]

Implantable hearing aids for children include two broad groups: 'electric hearing' with cochlear implants, and 'acoustic hearing' with bone-conduction implants (of which there are several types). For the great majority of children with profound sensorineural hearing loss (SNHL), the implant of choice is a cochlear implant.

COCHLEAR IMPLANTS

Cochlear implants are auditory implantable prostheses that electrically stimulate the spiral ganglion cells of the cochlear nerve directly in circumstances when the cochlear hair cells themselves do not function effectively to give adequate speech intelligibility. An implant consists of an external device with a microphone/processor and an internal device to stimulate the cochlear nerve. With improving technology, the indications for cochlear implantation are continually widening (see Chapter 94, Cochlear implants).

The first attempt to implant a cochlear implant (CI) was made in 1957 by Djourno and Eyries in Paris using a single-channel device.[3] These devices established that hearing could be achieved, but these early recipients used their implants largely in concert with lip-reading. In 1961, William House (otologist), John Doyle (neurosurgeon) and James Doyle (physicist) began work to implant a single-channel device. House's work continued into the 1970s, leading to the production of a 3M manufactured single channel device which was the first US Food and Drug Administration (FDA) approved model in 1984, and eventually to the Nucleus 22, which was the world's first commercial multi-channel CI with FDA approval.

The technology continued to improve with more widespread application of the product and greater confidence in its use. It was finally FDA approved for use in children in 1990. At this stage it was only approved for use for children above 2 years of age, but the age limit

was reduced to 18 months in 1998 and then further to 12 months in 2000. Since then, CIs have been routinely placed in children as young as 6 months, although in an anomaly the licence has never been amended to children below 12 months.

Design of implants

Although there are differences between devices, a basic arrangement is common with all the main manufacturers. There are four parts to the internal component: a magnet, a receiving induction coil (placed together to locate the outer transmitting coil by magnetic attraction), a processor and an electrode (**Figure 11.1**). A return electrode is also present, although this is usually incorporated in the housing of the processor unit.

An external processor is worn which communicates by induction with the internal receiver and also transmits power to activate the internal unit. There are various designs of the external processor to accommodate the different needs of users, but all have a microphone (or often two), and a speech processor, which employs a coding strategy to convert sound into electrical stimulation by the electrode. Various filters and coding strategies are used to give a variety of programs, optimized for speech, direction, music and so on. There is a magnet which holds the processor to the internal magnet, and a transmitter to send the signal by induction across the skin.

The number of active stimulating positions on the intracochlear electrodes varies from 12 to 22 according to the design of the implant. There are common themes to the types of intracochlear electrodes, although this is a field with relatively rapid development.

Figure 11.1 Internal part of cochlear implant (Cochlear N512).

POSITION WITHIN THE SCALA TYMPANI

The ideal position of the electrode is within the scala tympani where it sits close to the neural elements. Disruption of the basilar membrane by traumatic insertion or displacement into the scala vestibuli causes complete loss of residual hearing and may lead to worse outcomes.[4] Electrodes can be modiolar hugging (e.g. Cochlear Contour), Midscala (e.g. Advanced Bionics Midscala electrode) or lateral wall (e.g. MED-EL FLEX electrode).

SIZE

The cross-sectional size of the electrodes is reducing, mainly to improve the ease of insertion and to avoid trauma to the inner ear structures. The current electrodes allow preservation of residual hearing in many cases and may improve long-term cochlear health.

PLUGS, WINGS AND EXTRAS

MED-EL form electrodes have plugs to sit in the cochleostomy to help seal the cochleostomy and prevent cerebrospinal fluid (CSF) escape in abnormal anatomy with CSF 'gushers'. Other electrodes have wings to help positioning of the device (e.g. Cochlear Hybrid and EAS electrodes). Intracochlear positioners were tried in early devices, but these appeared to cause increased rates of bacterial meningitis and are no longer used.[5]

Custom-made electrodes for abnormal cochlear anatomy such as common cavities as well as split arrays used for ossified cochleas are also available.

Guidelines and funding

Prior to 2009, public funding in the UK allowed access for children to unilateral CI. However, in 2009, NICE published new guidelines which established that all eligible children were to receive bilateral simultaneous CI.[6] These guidelines were reviewed in 2011 after a multicentre audit and left unchanged.[2]

Given that binaural hearing skills are acquired early, there has been a preference for early implantation. This allows children rapid development of hearing and speech understanding by reducing deafness duration, maximizing the opportunity of early plasticity of the auditory system.[7] Children receiving a second implant several years after their first have demonstrated more significant asymmetries in brainstem and cortical function than those with a delay of less than 1 year or those implanted simultaneously.[8] These children have demonstrated poorer speech scores in the second ear compared to the first, stronger ear.

With the recognition of the benefits of bilateral and simultaneous cochlear implantation for children, a consensus was reached in 2010 by the Working group of European CI surgeons who released the European Bilateral Paediatric Cochlear Implant consensus statement. This stated that any infant or child who is an unambiguous CI candidate should receive bilateral simultaneous CI as soon as possible after the definitive

diagnosis is made and that surgery should be atraumatic to preserve cochlear function. Currently, more than 25% of children implanted before the age of 3 years have received bilateral implants worldwide whereas in children older than 3 years it is most likely that bilateral implants are inserted in a sequential manner.[7]

Prelingual deafness

Prelingually deafened children have not had the opportunity to organize the same cortical pathways as hearing children. Such deficits in maturation of the auditory cortex of prelingually deafened infants can be counterbalanced if hearing is introduced early. Animal models demonstrate a sensitive period of adaptation within the second to sixth months of life.[9] Similar outcomes have been noted in CI candidates in children. Prelingually deafened children implanted just prior to their teens show a delay in the development of normal morphology of cochlear-evoked potentials and prelingually deafened adults with CI do not achieve open-set speech discrimination.[10]

Thus there is a window or critical period of development during which it is important for these children to function at the same level as their hearing counterparts. With the introduction of newborn hearing screening (see Chapter 10, Management of the hearing impaired child), there has been an increased opportunity to diagnose these children early and therefore to implant them before 12 months of age. Parallelling this, there has also been an increased development of clinical and surgical skill, improved technology and a wider awareness of the benefit of speech understanding of implanted children, which have led to an increase in the number of children undergoing implantation prior to 12 months of age.[11]

Children implanted earlier have quicker language acquisition, earlier binaural skills, better language skills and can even develop along the normal path for language development.[12] Furthermore, data exist that early implantation increases the proportion of children in mainstream school and increases the cost utility of CIs significantly.[13]

Surgery in these young children is safe,[14–16] but barriers exist to early implantation. These include delays in scanning children, protracted behavioural audiology, parental concerns and waiting for surgery, but usually the greatest delay is referral from audiology/paediatric services for cochlear implantation. Newborn hearing screening, which exists in the majority of developed countries, identifies almost all of the children with congenital severe/profound hearing loss, but there is sometimes a reluctance to refer to cochlear implant centres without extended hearing aid trials and reassessment, which causes significant delays.[17]

Evidence does not yet exist that implantation below 6 months of age continues to improve outcomes further, and there is surgical concern that simultaneous implantation in very young infants carries a risk of bleeding which may be significant. Very early implantation (less than 6 months of age) is not yet a standard in paediatric implant surgery.

Postlingual deafness

Postlingual deafness in children is often due to meningitis or head injury. The outcome depends on the duration of deafness but most children who have had a period of hearing do well with CI. Recent changes in candidacy, however, have allowed other groups of postlingually deaf patients to benefit from CI. Children with auditory neuropathy spectrum disorder (ANSD) fall into this category and there is extensive ongoing work to understand this disorder better.[18, 19]

Partial deafness

An increasing number of studies have confirmed that partial deafness, most commonly high-frequency hearing loss with residual low-frequency natural hearing, is effectively treated in children with cochlear implantation.[20, 21] These children are hard to aid with conventional hearing aids because of the 'ski-slope' nature of the hearing loss. They may have limited ability to hear consonants and fricative sounds[20] though they have good low-tone hearing, which is important to appreciate music.[22] It is possible to implant with an approximately 90% chance of preserving useful hearing using a variety of electrodes.[23] Soft atraumatic electrode arrays and careful surgery are required to preserve the hearing.[24] There is an incidence of late loss of hearing a few months after the surgery, and it is usual to lose around 10–20 dB of hearing. There are speech processors that are designed to stimulate the high-frequency hearing using the electrical implant, and low-frequency hearing can be boosted with an acoustic hearing aid – combined in a single processor. This approach still allows access to interaural level and timing differences which facilitates localization of sound and binaural effects to increase speech understanding in background noise, compared to a conventional CI without low-frequency residual hearing. Once the residual hearing is below 80 dB this approach is ineffective as the residual hearing is no longer aidable – so, assuming a hearing loss due to the implant, it means that this 'hybrid' strategy is usually not attempted if the pre-operative low-frequency hearing is less than 60 dB HL.

A concern in children is that they will lose the residual hearing eventually during the natural process of ageing in the cochlear, a process which often occurs early in individuals with hearing loss. However, the modern hearing preservation electrodes are full or near full length and will function well even if the residual hearing is lost.

Single-sided deafness

Although the concept of cochlear implantation to restore bilateral hearing in adults is quite well established,[25] the value of using CROS (contralateral routing of sound) aids, bone-conducting aids or CIs is much less clear in children. Unilateral hearing loss in children results in educational deficits. Children with unilateral hearing loss are at increased risk of grade failures (24–35% vs

3% in normal-hearing children) and are more likely to require educational assistance (12–41%). Compared to normal-hearing siblings, these children have lower oral language scores, a 4.4 times risk of requiring an educational plan and a 2.5 times risk of having speech therapy.[26] Functional MRI scans have demonstrated neuroanatomical differences in auditory regions between single-sided deaf children and normal-hearing controls, but also in attention and executive control areas, and these children have a much higher incidence of behavioural problems[27] see Chapter 10, Management of the hearing impaired child.

CROS hearing aids are very poorly tolerated in children. Bone-conducting hearing aids (BCHAs) are more accepted, but the majority of children with single-sided deafness do not use them. A bone-conducting aid corrects the head shadow effect but does not give interaural level or timing differences to allow binaural hearing. Consequently, there are only modest improvements with a BCHA in localization or speech-in-noise comprehension. A CI will allow access to interaural level differences and will improve localization and speech in noise compared with BCHA, especially in situations where noise is presented to the normal-hearing ear and speech to the implanted ear. Interestingly, adults with unilateral CIs report a reduction in tinnitus; in children with hearing loss, tinnitus is often present but is rarely a major clinical problem.

There are only a few published reports of cochlear implantation in children with unilateral hearing loss.[28] However, it appears that this is as well tolerated by children as by adults who have had a sudden SNHL,[25, 29] and studies of prelingually unilaterally deaf children are underway. Early results are promising and this may be a viable treatment in the very near future. However, there may be additional issues to consider when treating congenital profound hearing loss in one ear. Animal studies indicate that, if unilateral deafness develops early and especially if it is congenital, then a period of time exists after which there is a shift in the cortical processing in preference of the hearing ear, which will influence the outcome of the second deaf ear if implanted.[30] The recommendation therefore from the animal work is to minimize the period of monaural stimulation as much as possible. Further data are necessary, investigating both short- and long-term implications of CI in single-sided hearing in children.

There will be additional prognostic factors to consider in children in addition to those in adults, such as whether the ear has ever heard, the presence of any malformations in the cochlea, the status of the nerve, the optimal window of time to implant, other comorbidities and their influence and so forth. As with bilaterally deaf children, minimizing the duration of deafness and early implantation will probably be very important in achieving good outcomes. However, significant questions remain about the cost-effectiveness of this treatment, and about the acceptability of a unilateral CI in older children and teenagers who may not wish to wear a hearing device for a unilateral disability.

Bilateral implantation

Bilateral CIs improve hearing for children with bilateral deafness beyond that which can be realized with a unilateral CI.[31] The aim in children is to promote important auditory processing that normally occurs when listening with two ears. Binaural hearing skills are normally acquired very early on; by 6 months of age, children with normal hearing show consistent lateralization of sounds by turning their heads. This means that small differences in interaural timing and level differences are detected and perceived by the auditory pathways. Speech comprehension in noise and localization are compromised when sound is heard from only one side or through only one CI but can be improved with bilateral CIs in both adults and children.[32]

Children receiving a sequential bilateral implant with an interval of several years have demonstrated significant asymmetries in brainstem and cortical function compared with those with a delay of less than 1 year or simultaneous implantation.[7] These children have demonstrated poorer speech scores in the second ear compared to the first, stronger ear.[33]

A most telling outcome of bilateral cochlear implantation is that children with two implants almost universally wear both devices and demand to have any equipment breakdowns (depleted batteries, broken components or device failures) repaired. Children and families also report improved hearing in the 'real world' even when outcomes measured in the audiological sound booth are minimal, which probably reflects the increased complexity of most listening situations beyond the quiet test environment.[34, 35]

Nevertheless, there are still many children around the world who receive a single implant or sequential implants. The main reason for this is financial. A number of children have residual hearing in the unimplanted ear and can benefit from bimodal (CI + hearing aid) amplification. There are also surgical concerns about bilateral simultaneous implantation (although there is no evidence to suggest a higher complication rate)[14, 36] and about possible vestibular dysfunction.

Assessment

Assessment for candidacy needs to be conducted in a specialized multidisciplinary team. In the UK the audiological guidelines for implant candidacy as per guidelines set by NICE[6] include severe to profound deafness (defined by thresholds of 90 dB or worse at frequencies of 2 kHz and 4 kHz without amplification) that preclude the child from attaining adequate speech, language and listening skills appropriate to age, developmental stage and cognitive ability with optimal acoustic amplification.

As with adults, assessment in children involves a battery of sound detection and speech perception tests, though the latter are somewhat limited in infants and in prelingual profound deafness. Preceding implantation, children undergo electrophysiological testing in the form of an auditory brainstem response (ABR) to obtain the true thresholds of the child. This may be acoustic and, if necessary, also

electric. In cases of auditory neuropathy, children may have an absent or abnormal ABR and thus otoacoustic emissions. Electrocochleography (ECoG) or eABR may also form part of the general battery of investigation for assessing candidacy for a CI. Aided thresholds and behavioural tests are important as well as speech perception tests but are conducted in an age- and disability-appropriate manner. Similarly, a hearing aid trial is offered to those children who may benefit from a trial or whose candidacy may be ambiguous, such as in the setting of ANSD.

In addition to the audiological factors that play a central role in candidacy, many other factors influence the outcome of children and thus a multidisciplinary assessment is very important.

Screening

Newborn hearing screening is now the accepted standard of care in most countries.[37] The National Health Service (NHS) Newborn Hearing Screening Programme (NHSP) was commissioned by the Department of Health in 1997 following a National Institute for Health Research (NIHR) Health Technology Assessment report which showed that a large number of deaf children were not being identified. Between 2001 and 2006 universal newborn hearing screening (UNHS) was implemented in England, Scotland, Wales and Northern Ireland and it is now estimated that, between 2006 and 2011, 74% of eligible children between 0 and 3 years had been implanted and 94% by age of 17.[38]

Medical assessment and imaging

A detailed history and examination should be conducted to evaluate the cause of the hearing loss, including prenatal and perinatal history to assess for risk factors some of which include TORCH infections (toxoplasmosis, other [syphilis, varicella-zoster, parvovirus B19], rubella, cytomegalovirus [CMV] and herpes infections), teratogens, prematurity, low birthweight, low APGAR scores, hyperbilirubinaemia, sepsis, meningitis and the administration of ototoxic medications. Other aspects of medical evaluation include a detailed family history, assessment for the presence of syndromes, immunization status and the presence of other otological disease which also involves the use of dedicated imaging of the temporal bone and knowledge of the status of the cochlear nerve.

Genetic hearing loss

The incidence of congenital hearing loss in the UK equal to or worse than 40 dBHL is somewhere in the order of 1 in 1000 children, with nearly 60% of these children having a genetic cause of deafness. It is estimated that 70% of genetic causes of hearing loss is non-syndromic and of these nearly 80% are inherited in an autosomal recessive manner.[39] The other 20% constitutes autosomal dominant, X-linked and mitochondrial DNA variant abnormalities. Although numerous loci of abnormalities have been characterized, the most common defect – constituting nearly 50% of all non-syndromic hearing loss – is a mutation in connexin 26 which codes for a gap junction protein beta 2.[40]

Syndromal deafness is less common and, although there are over 400 syndromes associated with hearing loss,[41] some common ones include Pendred, Usher syndrome and Jervell and Lange-Nielsen which are inherited in an autosomal recessive manner. Autosomal dominant syndromes include Stickler, branchio-oto-renal and Waardenburg syndrome.

Neurofibromatosis type 2, which can present later in childhood, is characterized by bilateral vestibular schwannomas (VS). Until recently, the presence of a schwannoma was considered a contraindication for CI. However, recent studies have reported successful outcomes of CI in untreated but stable VS, or in VS that has been stable following radiotherapy. When the tumour is growing and/or cochlear nerve preservation in not possible, an auditory brainstem implant (ABI) is another option.[42] (See Chapter 102, Surgical management of vestibular schwannoma, for more information).

Acquired hearing loss

Some of the causes of acquired hearing loss are outlined above. Although many such forms cannot be distinguished from genetic causes in young children, a thorough history may help provide helpful information, such as a history of prenatal infection with toxoplasmosis, syphilis, rubella, cytomegalovirus or herpes (TORCH microorganisms), and/or a perinatal history of prematurity, low birthweight, low Apgar scores and hyperbilirubinaemia.

Cytomegalovirus (CMV) is particularly interesting as early treatment with valganciclovir can prevent further hearing loss, or in a few cases bring about recovery in hearing. The optimum duration of treatment is not yet known, although 6-week to 6-month courses have been used. Early treatment appears to be more effective than later treatment.[43]

Meningitis, temporal bone trauma and rarely autoimmune inner ear disease may cause profound hearing loss and subsequent cochlear ossification. There have been reports of strategies that may be utilized to overcome partial and total ossification of the cochlea, including drilling out the basal turn, scalae vestibuli insertion and even the insertion of short or split electrodes. These procedures are, however, uncommon and therefore not well trialled and may risk damaging the neural elements. Nevertheless, they help emphasize the importance of a thorough medical and radiological evaluation in a multidisciplinary setting to inform the patient of the likelihood of success of implantation and also of the medical and psychosocial hurdles that lie in the path of postoperative rehabilitation.

Congenital malformations

About 20% of congenital SNHL can be attributable to inner ear malformations. Development in modern imaging and clinical experience has led to improved diagnosis and management of these disorders with respect to

cochlear implantation. The two main difficulties in surgery with malformations are CSF gusher and facial nerve abnormalities. Balanced with these is also a higher risk of meningitis with inner ear malformations with or without cochlear implantation.[44] Malformations were first divided into five main abnormalities: Michel deformity (labyrinthine aplasia), cochlear aplasia, common cavity, cochlear hypoplasia and incomplete partition. Minor adjustments have been recommended based on radiological differences of these abnormalities, subclassifying incomplete partition into three further categories depending on degree of severity. Type 2 incomplete partition, first described by Carlo Mondini, consists of a normal size cochlea with deficiency of the apical part of the modiolus and the corresponding interscalar septum. Together with a minimally dilated vestibule and a large vestibular aqueduct, a Type 2 incomplete partition forms the triad called the Mondini deformity. Incomplete partition Type 3 was reported in X-linked deafness.[45] In cochlear hypoplasia the normal cochlea turns do not form fully.

Pre-operative imaging therefore plays a very important role. An MRI not only is important in confirming the presence of a cochlear nerve in the presence of pre-lingual deafness, but will also show the turns of the cochlea and the anatomy of the vestibule. Furthermore, in cases where a CT scan may identify a narrow internal auditory canal, an MRI is also important to confirm that the nerve is present and not hypoplastic, especially when associated with certain syndromes such as CHARGE (coloboma, heart defects, atresia choanae, retardation of growth, genital anomalies and ear abnormalities). An absent cochlear nerve is a contraindication for CI. A finding of a hypoplastic cochlear nerve needs to be assessed individually, which may involve further imaging or an electrically evoked ABR.

High-resolution computed tomography (HRCT) helps to display the anatomy of the mastoid and the facial nerve as well as identify any malformations in the cochlea, the internal acoustic canal and other ear malformations. Altered facial nerve course is seen particularly in cochlear hypoplasia and common cavity. A hypoplastic cochlea may make for a difficult electrode insertion through a facial recess, as the round window may not be found in the usual area or the flatter profile of the promontory may mislead the surgeon. In these cases, alternate approaches such as a transmastoid labyrinthotomy, canal wall-down with a blind sac closure of the external ear canal or even a transcanal approach or insertion through the oval window may need to be employed.[46] Identifying the malformations also helps with the choice of electrode. Where the exact location of the neural tissue is not known, for example in a common cavity, an electrode with complete contact rings is likely to be more beneficial whereas in a hypoplastic cochlea, a shorter electrode may need to be used. Alternatively, in incomplete partition Type 2 all types of electrodes may be used.

Although there has been debate over which modality (MRI or CT) is more important in children, most implant teams utilize both CT and an MRI in the pre-operative planning of a CI as they each have their advantage and in the setting of malformations provide complementary information. It is important that these take place early in the workup of these patients to help guide them towards appropriate rehabilitation.

Auditory neuropathy spectrum disorder

First described in the mid-1990s,[47] auditory neuropathy is a hearing disorder characterized by the presence of outer hair cell function (evidenced by the presence of intact evoked otoacoustic emissions and/or cochlear microphonics) but abnormal or absent auditory brainstem response. However, due to the multifaceted nature of the aetiology of this condition and the recognition that the abnormality is not localized to the cochlear nerve, but may involve other defects such as inner hair cell/synapse or a synchronization of the signals being transmitted, the terminology was expanded to auditory neuropathy spectrum disorder (ANSD).[48]

Although the prevalence varies between studies and is difficult to quantify accurately, it has been estimated to be present in up to 1 in 10 children with permanent hearing loss.[49] The manifestation of this disorder involves difficulty hearing in noise, fluctuating sensitivity and speech perception scores not consistent with the level of residual hearing on the audiogram.

The aetiology can be multifactorial including genetic, congenital and acquired causes. Risk factors for ANSD include extreme prematurity (<28 weeks gestation), hyperbilirubinaemia reaching exchange transfusion levels, low birthweight or intrauterine growth restriction, and other neurological conditions such as hypoxic ischaemic encephalopathy and intraventricular haemorrhage (likely to occur in prolonged ventilation and sepsis). Genetic causes include Freidrich's ataxia, Charcot–Marie–Tooth disease and non-syndromic conditions such as DFNB9/*OTOF*.[50]

The electrophysiological tests constitute definitive diagnosis but, due to the heterogeneous manifestations of the ANSD, the recommended habilitation approach and choice of assisting device (whether it be a hearing aid or CI) remains controversial. The approach in children suffering with ANSD therefore has been to address patients on their own individual needs. Children with ANSD with cochlear nerve hypoplasia on MRI have worse CI outcomes and those with an absent cochlear nerve are unsuitable for CI.[51] Similarly, children who exhibit an atypical or absent ECAPs (electrically evoked compound action potentials) during implantation are also associated with poor outcomes.[52] Therefore, though a significant proportion of children will benefit from CI, some will benefit from amplification and some others who have bilateral cochlear nerve deficiency will not benefit from either intervention. Reasons for this heterogeneity with CI may be associated with their other comorbidities or with the failure of the electrical stimulus from CI to create adequate neural synchronization of signals. Thus a stepwise approach in a specialized multidisciplinary team is crucial to help guide the habilitation of these complex patients.

Chronic suppurative otitis media

Chronic suppurative otitis media (CSOM) was previously considered a contraindication to cochlear implantation. More recently, surgeons have applied a staged technique, in clearing the disease in the first stage and then performing an implant a few months later when the ear is dry. It is important to eradicate the source of any biofilms prior to the insertion of the CI. Some surgeons prefer to obliterate the mastoid cavity at the same time as the first operation, but the risk of future development of cholesteatoma remains and follow-up is made difficult due to the artefact created by a CI while using a diffusion-weighted MRI scan. In the presence of a dry, stable cavity, a blind sac closure and CI may be undertaken as a single stage.

Surgery

In most cases, cochlear implantation may be safely performed as a day-case[16] although in infants it is often sensible to admit overnight, especially if the surgery is in the afternoon.

INCISION

A postauricular approach with a small incision is preferable. The optimal incision for access has evolved over time. The general principles of the incision, irrespective of individual preferences, are that the incision should not be placed near the receiver/stimulator, to prevent skin breakdown and extrusion and also to ensure that blood supply to the region is not compromised. More complications relating to the skin are associated with a history of previous radiotherapy to the area.

APPROACH

Subperiostial flaps are raised and the mastoid exposed. A small cortical mastoidectomy is performed with a posterior tympanotomy. The round window should be identified and the surgically important landmarks include the incus short process, the facial nerve, chorda tympani nerve, incudostapedial joint and round window membrane.

RECEIVER/STIMULATOR PACKAGE

A bony recess which is specific to the device intended is drilled. The cortical bone is very thin in young children and at times the entire thickness of the cortical bone may be removed to the level of the dura to accommodate the receiver/stimulator and minimize skin complications. There are various ways to secure the electrode to prevent electrode migration, including drilling holes and tying sutures over the electrode or securing it with bone wax.

ROUND WINDOW VERSUS COCHLEOSTOMY

With the advent of electroacoustic stimulation in patients with residual low-frequency hearing there has been much interest in examining whether a round window perforation or cochleostomy is preferable. The advantage of a round window approach is that a small perforation can be made by a needle in the round window which helps seal the entry site of the electrode into the cochlea. Furthermore, there is no need for intracochlear drilling. A cochleostomy should be placed inferior to the round window. This involves meticulous drilling with exposure of the endosteum, which needs to be removed with a small hook thereby minimizing the trauma to the cochlea and preventing the entry of bone dust or blood into the cochlea. Both techniques have been shown to preserve low-tone hearing, and to minimize cochlear trauma. 'Soft surgery' may also minimize scar formation within the cochlea if the child needs revision surgery in the future.

Once the electrode has been inserted, the electrode entry is packed with fascia or periosteum at the site of entry to prevent leak of perilymph. In the case of residual hearing it is important not to overpack the middle ear as it may cause a degree of conductive hearing loss of the residual hearing frequencies.

NEURAL RESPONSE TESTING

Most units in the UK perform intra-operative testing to confirm electrode integrity and measure impedance.

BILATERAL SURGERY

This requires bilateral facial nerve monitoring. Care must be taken to plan the placement of the devices at the same level behind the ear so there is symmetry when the patient wears the external device.

POST-OPERATIVE RADIOGRAPH

A post-operative X-ray (Stenver's view) helps to confirm electrode insertion, identify potential tip foldover, and give a reference for the correct placement of the electrode in the cochlea should there be future problems. If required, radiographs, fluoroscopy and/or image guidance may also be used intra-operatively in cases of expected difficulty such as revision cases or congenital malformations.

Complications

Complication rates in paediatric cochlear implantation are in the order of 10% with major complications constituting < 3%. Malformations of the cochlea make for a higher incidence of complications.[14, 36, 53]

INFECTIONS

Wound infections constitute nearly half of all complications in children and a course of peri-operative antibiotics is important to minimize this.

FACIAL NERVE INJURY

With the use of facial nerve monitoring facial nerve paresis in a paediatric population is rare, though a rate of chorda tympani nerve injury between 5% and 20% has been reported.[54]

CSF FISTULA

This is rare and can occur early or late with an incidence of 1%. Secondary meningitis may occur but is extremely rare. It is important to pack the cochleostomy adequately to prevent this, especially in the presence of an enlarged vestibular aqueduct.

DEVICE FAILURE

The rate of device failure of contemporary CIs has been reported as <1%. Late device failure is difficult to predict and may even be difficult to diagnose in the setting of a developmentally delayed child or one with numerous comorbidities.

CHOLESTEATOMA

Secondary cholesteatomas, though rare, have been reported. It is important to stabilize any ear disease prior to embarking on cochlear implantation. Early retraction pockets may be repaired by cartilage tympanoplasty. Secondary cholesteatomas may need a radical mastoidectomy with blind sac closure and removal of all squamous epithelium but the inability to monitor the cavity for recurrence is a drawback.

POST-OPERATIVE MRI

If necessary for the patient, an MRI can be conducted in the presence of CI using a 1.5 Tesla MRI scanner. If the magnet of the receiver stimulator is left *in situ*, an ovoid void is created of approximately 60 mm × 100 mm in size compared to 35 mm × 55 mm size if the magnet is removed. The image quality is inferior in the immediate region of the void surrounding the receiver/stimulator but the rest of the image is of high quality. Tight head bandaging is recommended to avoid movement of the receiver/stimulator. Pain and discomfort during scanning can be alleviated by the injection of local anaesthetic to the area of the receiver/stimulator prior to head bandaging. Occasionally, movement of the internal magnet occurs, but this can usually be corrected by replacement of the magnet at a later stage.

MED-EL now have a rotating magnet design which allows the magnet to move within the implant to align with the magnetic field. This allows use of a 3T MRI and reduces the risk of discomfort and dislodgement of the magnet. However, the artefactual degradation of the image on the ipsilateral head is still present.

Post-operative rehabilitation

Specialist multidisciplinary support including audiologists, speech therapists and educators is crucial to the successful rehabilitation of implantation. Patients are typically seen at 2–4 weeks for 'switch on' and ongoing follow-up and support are required to enable optimal use of the implant and for acquiring appropriate speech and language development.

There is no doubt that there are multiple benefits from CI in children. After only 1–4 years of implantation, paediatric patients can demonstrate speech and language skills equivalent to their hearing counterparts. Prognostic factors influencing outcome include age at implantation, age of onset, residual hearing, use of hearing aids, other comorbidities, family support, post-operative rehabilitation and consistent use of the implant. Despite the best support and rehabilitation, in certain children, especially those with complex needs, it is more important to measure outcome with a quality-of-life measure than with traditional measures of outcome. In these children, it may be unrealistic to expect the development of oral language and therefore it will not accurately reflect the benefit that CI can give in providing the awareness of sound in the life of a child who is already deprived of many other psychological, sensory and social inputs.[55]

Extended candidacy

Different criteria for candidacy have been adopted in different health economies. In the UK the NICE (National Institute for Health and Care Excellence) guidelines determine candidacy: for children this is 90 dB hearing loss at 2 kHz and 4 kHz, with evidence of delayed speech and language development. However, children with hearing above these thresholds benefit from cochlear implantation in certain circumstances. There are numerous reports of children with asymmetric hearing loss benefiting more from the implanted side than the hearing aid side.[55] Furthermore, the outcomes after cochlear implantation in around 80% of children with hearing thresholds of 80–90 dB are better than can be achieved with hearing aids. This raises the possibility that current guidelines are too restrictive, and that a wider range of severely deaf children could be offered CIs, especially as residual hearing can usually be preserved allowing hybrid electroacoustic stimulation in both ears.[56]

Future technologies

The technological advancement of auditory implants continues apace and, in fact, it is likely that any report on this will be out of date within a few months, and certainly within several years. The following current areas of development look to be fruitful.

ELECTRODE DESIGN AND INSERTION

There are a number of electrodes developed by commercial implant companies which allow hearing preservation and deep insertion into the cochlea for 'complete cochlea coverage', and custom electrodes for anomalies in cochlea anatomy. Insertion forces appear to be crucial to maintain a healthy cochlea for long-term health of the inner ear, as well as hearing preservation. Robotic insertion to reduce these forces further is an active area of research interest with promising early studies.

NEUROTROPHINS AND GENE THERAPY

A CI is a promising conduit for delivering growth factors directly or by gene therapy techniques, as well as electrical stimulation to prolong and increase neural response. Recent animal studies have shown great promise in animal models, but these have not yet been translated to human trials.[57]

TOTALLY IMPLANTABLE IMPLANTS

Adults implanted with totally implantable devices have found outcomes limited by the subcutaneous microphone.[58] Newer devices may use the ossicular chain as a microphone for middle ear stimulation, and the translation of this technology to CIs is inevitable.[59] However, at this point, no totally implantable CIs have been used in children.

IMPROVED PROCESSING STRATEGIES

Sound processing strategies to improve the appreciation of music and to allow speech discrimination in background noise are actively being developed and released. Bidirectional microphones to determine sound direction, and communication between bilateral cochlea implants, along with automatic programmes that especially suit children, give better outcomes and are often retrospectively available to previous versions of CIs.

IMPROVED USER EXPERIENCE

Already, CI processors are routinely available which are compatible with add-on devices by Bluetooth™, or Wi-Fi signals. The processors are water-resistant, and in some cases waterproof, to allow swimming and showering while hearing. Off-the-ear solutions to minimize the visibility and improve the comfort of the processors are also helpful to some patients, although CIs still use significant power and so battery size can limit the size of devices. Finally, data logging and feedback to audiologists to help with tuning and remote management of devices to save on clinic visits can make life easier for patients and their families.

AUDITORY BRAINSTEM IMPLANTS

Auditory brainstem implants (ABI) are auditory prostheses designed to provide electrical stimulation directly to the cochlear nucleus in the absence of a functional cochlear nerve (**Figure 11.2**). First used in 1979 by William House and William Hitselberger after removal of an acoustic neuroma, their use has been mainly reserved in the setting of NF2.[60] Colletti et al first reported their use in a paediatric setting.[61] Use in prelingually deaf children remains primarily in those children in whom CI is contraindicated, for example in complete labyrinthine aplasia or congenital malformations with cochlear nerve hypoplasia or aplasia. In postlingual deafness, an ABI may be indicated in tumour or non-tumour patients. Tumour patients include patients affected with NF2 or bilateral VS whereas non-tumour patients include those with bilateral severe cochlear ossification (which may be secondary to meningitis), gross cochlear destruction from otosclerosis, other surgical conditions precluding CI, and fractures through the IAC causing cochlear nerve avulsion or unmanageable facial nerve stimulation post CI.[62]

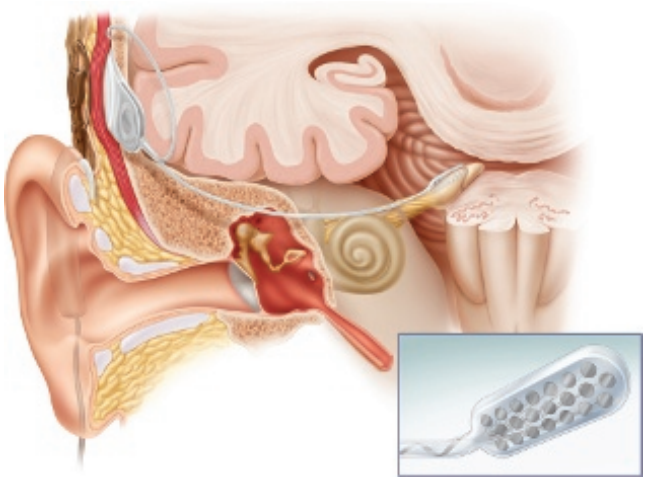

Figure 11.2 Schematic diagram of ABI placement on auditory nuclei. The insert shows the panel of electrodes.

Long-term results are still pending but audiological outcomes are not seen to parallel CI. Open-set speech discrimination only occurs in occasional cases and therefore a CI where possible should always be the first option. Furthermore, a CI is easier and safer to implant, with a much lower risk of life-threatening complications. Prior to considering a paediatric ABI, therefore, very careful radiological assessment and electrophysiological testing (e.g. eABR) is crucial. In the setting of prelingual deafness, outcome will depend on early intervention and therefore it is important to identify candidates through newborn screening and subsequent medical and radiological assessment.

The optimal age for elective intracranial surgery is 18–24 months, but in some experienced centres the minimum age for an ABI can be regarded as low as 1 year. Earlier intervention carries the risk of hypovolaemia through CSF and blood loss, poorly formed lateral recess size and higher risk of brain swelling post-op but delayed intervention loses the benefit of cortical plasticity. Parents and carers need to be counselled prior to embarking on surgery that for prelingual recipients programming and rehabilitation is a lot more intensive that for CI and the results are not as good.

BONE-CONDUCTION HEARING IMPLANTS

Children with malformations of the external and middle ear or children who cannot use air-conduction hearing aids may be aided by bone-conduction hearing implants

(BCHIs). Surgical reconstruction of congenitally abnormal ears is performed in some centres but even in successful cases an air–bone gap of 20–30 dB may remain. Consequently, bone-conduction hearing aids have become widely used and with time, the indications, surgical techniques and number of available devices have continued to evolve.

Indications

Current indications for use of bone conduction devices in a paediatric setting include:

- conductive hearing loss
- congenital causes such as atresia or microtia
- acquired causes such as chronic otitis media or ossicular pathology
- chronic discharging ear (such as CSOM or recurrent otitis externa)
- unilateral mixed or profound hearing loss
- failure of the child to tolerate a conventional hearing aid.

Bone-anchored hearing aids

The first bone-anchored hearing aid (BAHA) was implanted in Sweden in 1977[63] and became commercially available in 1987. These hearing aids function by transmitting sound through bone via an osseointegrated abutment (Figure 11.3).

AGE OF IMPLANTATION

The US Food and Drug Administration have set a minimum age for paediatric use at 5 years. However, the minimum age for implantation is debated and there is no fixed worldwide guideline. In 2005 an international consensus was issued regarding bone-conduction hearing aids which recommended that surgery should not be undertaken prior to the age of 2–3 years. This was to allow the skull thickness and conditions to reach a minimum thickness to fit the fixture and allow osseointegration.[64]

Though successful implantation has been reported in a child as young as 14 months, the complication rate is inversely proportional to the age of implantation.[65] It is important to stimulate hearing as early as possible, and therefore in children too young for implantation the use of a bone-conduction hearing aid via a Softband™, which holds the hearing aid to the skin of the scalp via a metal or elastic headband, is advocated from about the age of 3 months.

Figure 11.3 Diagram of percutaneous bone-anchored hearing aid with titanium fixture in the bone (1), abutment (2) attaching to the fixture and hearing aid (3) (placed later and removable by patient).

SURGICAL CONSIDERATIONS

In the past BAHA surgery on children was staged, but tissue-preserving single-stage implants mean this is no longer necessary. The linear insertion technique eliminates the need for a skin flap. More recently, changes in device design have enabled preservation of soft tissue which both decreases the complication rates and also significantly reduces surgical time. However, in children a longer time to osseointegrate is recommended to compensate for the thinner calvarium.

COMPLICATIONS

Despite the advantage of the bone-conduction hearing technology, major short- and long-term complications of the percutanous implants in children include soft-tissue complications and fixture loss. Classification of soft-tissue complications are staged by Holger, ranging from 0 to 4, with 0 being reaction free skin around the implant and 4 being overt infection requiring implant removal. These complications seem to affect children more than adults and are associated with a higher rate of fixture rate loss (up to 14% over 15 years) in the paediatric population.[66] A much higher rate of fixture loss occurs when the shorter 3 mm fixture is placed, and so a 4 mm fixture should always be used. This involves depressing the dura during the implantation in all but the largest children.

CURRENT DEVICES AND RECENT MODIFICATIONS

Cochlear

In 2010, Cochlear introduced changes to the osseointegrated titanium fixture which included a wider base (4.5 mm versus 3.75 mm) for increased stability, smaller treads at the implant neck to improve load distribution and a Tioblast™ coating for faster osseointegration to the BI300 system. In 2012, it further modified the abutment with a hydroxyapatite coating (BA400) which

eliminated the need for soft-tissue reduction. The abutment sizes became longer to adapt to the thickness of the skin. Challenges in a paediatric setting include accommodating for growth and increases in soft-tissue thickness especially during puberty. The abutment is available in various lengths and may be changed to adapt to the child's growing needs.

A new transcutaneous system, the BAHA Attract, uses a magnet to secure the BAHA. While a major advantage in a paediatric setting is eliminating the soft-tissue complications of a BAHA, disadvantages include problems with future MRI scans and possible dampening of the signal through the skin.

Ponto

Oticon Medical introduced the Ponto in 2009, which is another bone-anchored hearing system. Similar to the Cochlear BAHA system, it comprises an implant, percutaneous abutment and external processor and – similar to the Cochlear BA400 system – has long abutments available which enable tissue-preservation surgery. The results are comparable and it is a well accepted option for a bone-conduction hearing device.

Middle ear implants

Middle ear implants, in selected patients, offer an option of hearing rehabilitation in conductive, mixed or SNHL. A worldwide consensus regarding the application of the vibrant soundbridge (VSB) found it is viable for use in children and adolescents if they have adequate anatomy to place the VSB, but each case and each treatment option should be weighed on its individual advantages and disadvantages.[67] The floating mass transducer may be connected to the incus long process, stapes remnant or round or oval window.[68, 69] The patient should be counselled about surgical issues and MRI compatibility and the risk of dislocation of the device with future MRI.

Bone Bridge

A transcutaneous bone-conduction hearing aid, which is indicated in conductive or mixed hearing loss as well as single-sided hearing – the Bone Bridge – was released by MED-EL corporation in September 2012. The device consists of an external audio processor and an internal bone-conduction implant. The internal component has an internal receiver coil, a magnet, a demodulator and a bone-conduction floating mass transducer (FMT) that is secured to the bone by two titanium screws. The power to drive the FMT and sound energy are transmitted transcutaneously via an inductive link to the internal coil, processed by the demodulator and then relayed to the BC-FMT, which then tranduces the signals into mechnanical energy. Osseointegration of the titanium screws is not thought to be crucial.

CONCLUSION

New devices continue to be introduced and current technology continues to evolve. With time, new indications continue to arise in the treatment of paediatric deafness. Despite the rapid introduction of new technology, it is important that the introduction and application of this into patient care be conducted in a rigorous evidence-based manner. To achieve this, it is essential that good collaboration continues between clinicians and industry and, most importantly, that regular and thorough feedback is obtained from patients and caregivers regarding the influence of new developments on their quality of life.

FUTURE RESEARCH

- ➤ Current areas of development in cochlear implant technology are discussed above.
- ➤ Fully implantable bone conducting devices will avoid skin complications in future but must increase gain to be suitable for all patients.
- ➤ The optimum rehabilitation of the child with single-sided deafness is still in evolution and awaits stronger evidence of benefit.

KEY POINTS

- Auditory implants can rehabilitate children with conductive and sensorineural hearing loss.
- Early, preferably bilateral, rehabilitation improves outcomes.
- Identification and rapid assessment of deaf children is essential.
- The technology is advancing quickly and should result in better outcomes in the future.

CHAPTER 12

CONGENITAL MIDDLE EAR ABNORMALITIES

Jonathan P. Harcourt

SEARCH STRATEGY

Data in this chapter may be updated by a search of the Guidelines databases on www.library.nhs.uk, the Cochrane library and TRIP databases using the keywords: congenital, middle ear and ossicle. This was supplemented by a PubMed search using the keywords: congenital and middle ear or ear, ossicle.

INTRODUCTION

Conductive hearing loss in children is usually acquired. The most common aetiology is otitis media with effusion (OME) but it may be the result of chronic otitis media (mucosal or squamous). In the presence of severe congenital deformity of the external ear, associated abnormalities of the ossicular chain are common but in isolation they are rare and often have a delayed diagnosis, particularly if unilateral.

A variety of non-ossicular congenital middle ear abnormalities may also be associated with ossicular deformities. They may be symptomatic in themselves or be important aspects of other middle ear conditions and surgery. They include:

- persistent stapedial artery
- anomalous course of the facial nerve
- congenital perilymphatic fistula
- high jugular bulb
- aberrant internal carotid artery.

Definition of congenital ossicular abnormalities

Congenital ossicular fixation and defect is defined as a malformation affecting the ossicular chain, present at birth, which leads to a dysfunction of the ossicular mechanism due to immobility or discontinuity of the ossicular chain.

Major malformations involve both the tympanic cavity and the external ear (ear canal and pinna) and are described as congenital aural atresia or microtia. In association with these conditions, in either sporadic cases or as part of a syndrome such as Treacher Collins or Goldenhar, there may be a variable degree of ossicular abnormality and there may also be associated inner ear dysplasia.

Minor malformations affect the ossicular chain alone and the tympanic membrane and ear canal are normal.

CLASSIFICATION OF CONGENITAL OSSICULAR ABNORMALITIES

There have been many published classifications based on individual surgeons' series.[1] Cremers' classification describes the largest published series of operated minor congenital ear anomalies (104 cases).[2] It has been modified by Tos[3] and seems to be the most inclusive and descriptive of all the published schemes (**Table 12.1**).

Minor malformations are divided into four main groups, each of which may be subdivided: isolated stapes ankylosis, ankylosis with other ossicular anomaly, isolated ossicular anomaly, and aplasia or severe dysplasia of the oval or round windows.

TABLE 12.1 Cremers' classification of minor congenital anomalies of the ossicular chain in 144 operated ears (modified by Tos) (reproduced from Tos,[3] with permission)

Class	Main anomaly	Subclassification	% ears operated (*n* = 144)
1	Isolated congenital stapes ankylosis (or fixation)	1. Footplate fixation a. Normal stapedial arch b. Monopodial stapedial arch c. Monocrural stapedial arch 2. Stapes suprastructure fixation a. Elongation of the pyramidal eminence b. Stapes - pyramidal process bony bar c. Stapes - facial canal bony bar d. Stapes - promontory wall bony bar e. More than one bony bar	30.6
2	Stapes ankylosis associated with another congenital ossicular chain anomaly	1. Incus and/or malleus deformation or aplasia of the long process of the incus 2. Bony fixations of the malleus and/or incus	38.2
3	Congenital anomaly of the ossicular chain but mobile stapes footplate	**Discontinuity of the ossicular chain** Aplasia of the long process of the incus Dysplasia of the long process of the incus	15.3
		Epitympanic fixation Malleus Anterior Superior Lateral Incus body Superior Lateral Medial Short process of the incus In incudal fossa **Tympanic fixation** Of the malleus handle Of the long process of the incus	6.3
4	Congenital aplasia or severe dysplasia of the oval or round window	**Aplasia**	6.9
		Dysplasia	
		Crossing (prolapsed) facial nerve Persistent stapedial artery	2.1 0.7

INCIDENCE OF CONGENITAL OSSICULAR ABNORMALITIES

Bergstrøm[4] reported that out of a group of 687 children with congenital hearing loss, only eight (1.2%) were found to have isolated middle ear anomalies. There is no systematic report of absolute incidence though Thringer et al.[5] reported the incidence of conductive hearing loss, severe enough to require amplification, to be 0.6:1000. These cases were all bilateral. The incidence of unilateral cases is unclear.

Cremers and Teunissen's series[2] does provide a relative incidence with stapes ankylosis with another associated ossicular chain anomaly being the most common finding (38%) with isolated stapes ankylosis being the other largest group (30%). Isolated anomaly of the ossicular chain was found in 22% and aplasia or severe dysplasia of the oval or round windows in 10%.

In a Japanese surgical series, Hashimoto et al.[6] reported a much higher rate of incudostapedial joint defects, either in isolation or with stapes fixation, making up nearly 50% of cases.

The majority of Cremers' cases were sporadic although in 25% they were part of a recognizable congenital syndrome including branchio-oto-renal, hemifacial microsomia, Klippel–Feil, Crouzon and Pfeiffer syndromes.

CLINICAL PRESENTATION OF CONGENITAL OSSICULAR ABNORMALITIES

Children with bilateral ossicular abnormalities will often present at a similar age to children with OME because of poor hearing performance and speech delay. It is not unusual that the children are managed with one or more sets of ventilation tubes before the diagnosis is made. The observation of a conductive hearing loss, normal tympanic membrane and normal middle ear pressure should lead to the general diagnosis.

INVESTIGATION OF CONGENITAL OSSICULAR ABNORMALITIES

Audiometry

There is an average threshold of approximately 50 dB, producing a flat air conduction line, with no low-frequency bias as with otitis media. There is an average air-bone gap (ABG) of 35 dB at 0.5-2 kHz, either due to Carhart's effect or because of the presence of an underlying sensorineural hearing loss. Tympanometry usually demonstrates a normal middle ear pressure with reduced compliance due to fixation of the ossicular chain.

Imaging

High resolution computed tomography (CT) scanning remains the primary imaging modality though complementary magnetic resonance imaging (MRI) studies may demonstrate associated labyrinthine and internal auditory meatal abnormalities. CT virtual endoscopy may offer a further mode of presenting the images for pre-operative surgical planning although currently it fails to image satisfactorily the stapes suprastructure.[7]

Exploratory surgery

The diagnosis may only be made during a tympanotomy, but an interesting alternative to lifting the tympanic membrane is to attempt to visualize the ossicles via Eustachian tube and middle ear endoscopy.[8] The innate risk of damage to the ossicles and extent of view with this technique is not yet well defined.

PRINCIPLES OF MANAGEMENT

As with all cases of hearing loss, children and adults with congenital ossicular abnormalities need to be managed with thought to their overall hearing performance and requirements.

In the presence of a bilateral moderate hearing loss due to a maximal or near-maximal conductive hearing loss, some form of auditory rehabilitation should be recommended. For the majority, this will mean a conventional unilateral or bilateral air conduction hearing aid. With minor malformations there should be a stable external ear canal as a platform for amplification. If the patient develops local complications in the external ear canal, such as recurrent or chronic otitis externa, a bone-anchored hearing aid (BAHA) would be a suitable alternative.

Unilateral cases are less well defined in terms of best management. In the presence of ipsilateral tinnitus, amplification may act as a tinnitus masker. A hearing aid may improve the patient's hearing performance in background noise and optimize sound localization. The positive benefits need to be weighed against the potential morbidity of a conventional hearing aid, which includes the occlusion effect, otitis externa and the body image issues involved in wearing hearing aids, particularly among children and adolescents.

Surgery for congenital ossicular abnormalities should only be undertaken by dedicated otologists with experience of complex middle ear reconstruction. When the diagnosis has been made in childhood, consideration for surgery should be preceded by an adequate trial of amplification. Whatever middle ear surgery is contemplated, but particularly with stapedotomy, there is a significantly higher risk of delayed sensorineural hearing loss due to sporadic episodes of acute otitis media in children under 10 years of age. By this time it may be appropriate to involve the child in the decision-making process or to wait until adolescence or adulthood to allow the patient to come to their own decision regarding surgical treatment.

A pre-operative CT scan would be a mandatory investigation to attempt to identify the ossicular abnormality, but also to visualize any other middle or inner ear abnormality such as an anomalous facial nerve, congenital cholesteatoma, aberrant vascular structures or labyrinthine dysplasia.

MANAGEMENT OF SPECIFIC CONGENITAL OSSICULAR ABNORMALITIES

Isolated stapes ankylosis

Tos[3] subdivided Cremers' basic classification to separate stapes ankylosis into two main groups, depending on whether the footplate or suprastructure is fixed (see **Table 12.1**). In 20% of cases the suprastructure may be abnormal, with one crus being absent (monocrural) or there being no recognizable crura but instead a single strut (monopodial).[9]

Congenital stapes ankylosis at the level of the footplate was first described by Shambaugh[10] in 1952. He emphasized the clinical contrast to otosclerosis, in particular that the margins of the congenitally fixed footplate and the annular ligament are difficult to visualize since the footplate bone blends into the bone of the surrounding otic capsule.

The pathological processes leading to stapes footplate fixation are unclear. Lindsey et al.[11] concluded from a temporal bone study that fixation occurs due to failure of the annular ligament to differentiate from the lamina stapedialis. This leads to continuous ossification from the otic capsule to the footplate. Nandapalan and Tos[12] argue, however, that the cause is a subsequent ossification of the already-formed annular ligament, around 16 weeks of gestational age, because any arrest of development at this stage would be likely to cause a more widespread inner ear abnormality.

An ossified stapedial tendon may develop because of a failure of its precursor to form a tendon and instead become cartilaginous like the neighbouring precursor of the pyramidal eminence.[12] This subsequently becomes ossified, fixing the stapes. The other rare forms of fixation of the stapes suprastructure are probably caused by the

persistence of the contact between the developing stapes and Reichert's cartilage, which is usually lost as the stapes forms.

Surgery for congenital stapes footplate fixation

Pre-operative scanning may demonstrate labyrinthine dysplasia, any degree of which should alert the surgeon to an increased risk of inner ear damage. In particular, a dilated fundus of the internal auditory meatus (IAM) should be sought. This is a feature of X-chromosome-linked progressive mixed deafness with perilymphatic gusher.[13] The dilation of the IAM is associated with a defect allowing communication of cerebrospinal fluid (CSF) with the labyrinthine, which is released through a stapedotomy and leads to a high rate of sensorineural hearing loss. The high perilymph pressure may be the cause of the apparent conductive element of the hearing loss, which may mask the principal sensorineural nature of the raised air conduction thresholds. A previously reported association with a 'patent cochlear aqueduct' has been shown to have no histological basis in temporal bone studies.[14] The aqueduct is normally patent and cases of so-called 'widely patent' ducts seem to relate to a flaring on the medial aspect of the duct as it enters the jugular foramen. There is little variation in the duct as it passes through the otic capsule.

The surgical technique is similar to otosclerotic stapes ankylosis. A common feature of congenital fixation is the presence of thick anterior and posterior crura. To reduce the risk of inner ear damage these may be vaporized with a KTP laser.[15] This may also be used to aid the formation of a stapedotomy as the footplate is often thick.

Reported outcomes of surgery from specialist centres for isolated congenital fixation of the stapes nearly match the outcomes in the literature for adult series for otosclerosis, with more than 70% closure of the ABG to 20 dB or less.[6, 16] However, excellent results, with an ABG of less than 10 dB, seem less common than with surgery for otosclerosis.[17] Rates of inner ear damage are also comparable.

Surgery for stapes suprastructure fixations

In the very rare cases where the footplate is mobile but the suprastructure is fixed, removal of the bony bar can be achieved using a CO_2, argon, potassium titanyl phosphate (KTP) or erbium laser or with a microdrill. Traditionally, this has been achieved with a curette or by fracturing with good results.[12]

Isolated non-stapes middle ear anomalies

There is a large variety of described anomalies among case reports in the literature and these represent the different subclasses in Table 11.1. In addition, the stapes itself, though mobile, may be dysplastic.

The surgical management is by appropriate tympanoplasty. If there is attic fixation, then a separate atticotomy is necessary to expose the problem and allow surgical treatment. If there is a bony bar, this can be relieved by laser, microdrill or curette. A similar approach is used with fixation of the malleus handle by an atretic plate. With the absence of the long process of the incus, an interposition prosthesis is indicated.

Stapes ankylosis associated with other deformities

The potential anomalies are as described when found in isolation. Stapedotomy is again indicated but it may be necessary to consider a mobilization of the ossicular chain if there is epitympanic fixation or a malleovestibulopexy following removal of the head of the malleus.[6] Though surgery is difficult in cases of a deformed incus or fixations of the incus and malleus in the attic, reported results are good.[17]

Congenital aplasia or severe dysplasia of the oval and round windows

The stapes crura are usually poorly developed and do not reach the region of the footplate and may be embedded in the facial nerve. In such cases the course of the facial canal is often anomalous.

With such a severe abnormality preventing conduction of sound energy into the inner ear and particularly with the risk of a facial palsy with an anomalous facial nerve, auditory rehabilitation with hearing aids or a BAHA may be most appropriate. The potential surgical solutions have significant drawbacks. A fenestration procedure would leave a cavity requiring long-term care. A neo-oval window operation, in which a *de novo* entrance into the labyrinth is either drilled on the promontorial or even on the rostral side of the Fallopian canal, has a high risk of inner ear damage.[2]

NON-OSSICULAR CONGENITAL MIDDLE EAR ABNORMALITIES

Persistent stapedial artery

The stapes forms around the stapedial artery, leading to formation of the obturator foramen. By 10 weeks of development the artery atrophies, leaving a patent foramen underneath the arch of the stapes. If persistent, it arises from the petrous internal carotid artery (ICA), traverses Jacobsen's canal for a short segment, exits at the promontory, passes through the stapes obturator foramen and enters the Fallopian canal close to the cochleariform process. The persistent stapedial artery (PSA) passes anteriorly, exiting the canal at the geniculate ganglion, and passes into the extradural space of the middle cranial fossa, where it gives rise to the middle meningeal artery. In the presence of a PSA, the foramen spinosum is usually

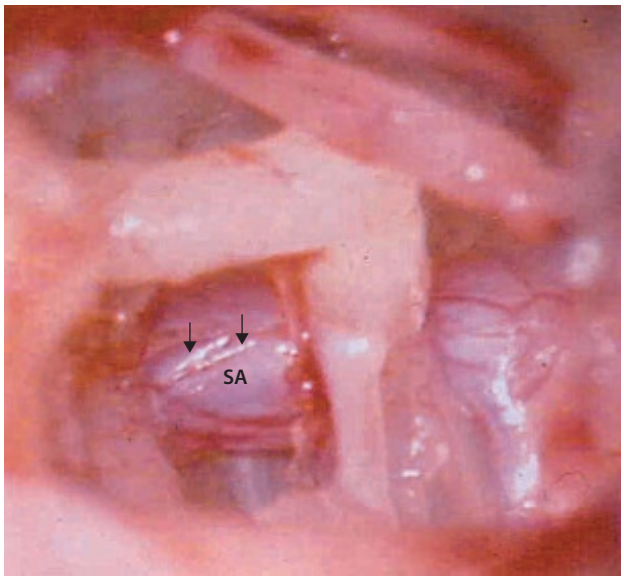

Figure 12.1 Finding during stapes surgery – a persistent stapedial artery (PSA).

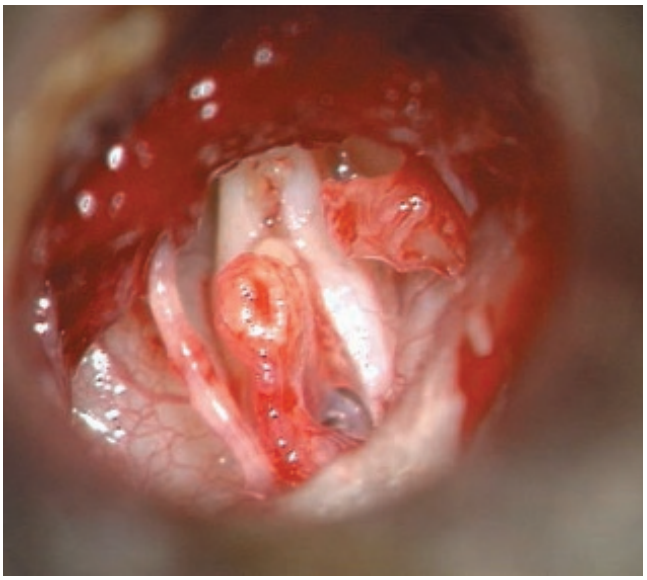

Figure 12.2 Stapes may be normal and mobile, even in the presence of a bifurcated facial nerve.

absent and the ICA may have an aberrant course due to its collateral formation secondary to a segmental agenesis of the ICA.[18]

A PSA may present as a vascular mass within the middle ear,[18] found either during otoscopic examination of the ear or during middle ear exploration, but is often asymptomatic or the cause of pulsatile tinnitus and has no relationship to conductive hearing loss.

It may also present as a chance finding during stapes surgery (Figure 12.1). It is unclear whether the discovery of a PSA during a stapedectomy indicates a congenital fixation or is coincidental in cases of otosclerotic stapes ankylosis.

Traditional teaching has been that the presence of the artery is an absolute contraindication to stapedectomy, partly as it was thought that damage to the artery would lead to ischaemic damage to the facial nerve. Govaerts et al.,[19] however, reported 12 cases, including two of their own, in which the outcome of surgery was satisfactory. In three cases the artery was damaged or clipped without any post-operative complications.

Anomalous course of the facial nerve

The Fallopian canal may show dehiscence or have an anomalous course within any part of its course within the temporal bone. This has great surgical significance and may be a hazard in all forms of tympanomastoid surgery. An abnormal course is particularly common with microtia or with dysplasia of the oval and round windows and there should be a high index of suspicion in any surgery for congenital conductive hearing loss and the use of the facial nerve monitor is highly recommended.

The Fallopian canal arises from the otic capsule and the second branchial arch and a theory of the cause of an anomalous facial nerve is a failure of fusion of the two. As there is a relatively high association with other ossicular abnormalities other than of the stapes, a local teratogenetic effect may also be responsible.

Rohrt and Lorentzen[20] classified facial nerve displacement in the middle ear into four groups:

- facial nerve partially obliterates the stapes footplate
- bifurcation of the facial nerve
- facial nerve rests on the footplate with deformed stapes or oval window
- facial nerve rests on the promontory.

Although these abnormalities are often found in association with stapes fixation, it may be normal and mobile, even in the presence of a bifurcated facial nerve (Figure 12.2).

Congenital perilymphatic fistula

Congenital perilymphatic fistula (PLF) is an abnormal communication between the middle and inner ear. It may be associated with:

- microfissures around the oval and round windows
- labyrinthine or IAM dysplasia.

The diagnosis is controversial as there is no reliable preoperative test which identifies the condition and management is based on the suggestive diagnosis of a child presenting with progressive or fluctuating sensorineural hearing loss, possibly associated with vertigo. Weber et al.[21] define the intra-operative diagnosis as being based on the identification of clear fluid which reaccumulates with anaesthetic Valsalva or Trendelenburg manoeuvre. Beta-transferrin positive samples are consistent with CSF being a constituent of the leak and this will be a feature of some but not all cases of PLF, usually associated with

labyrinthine or IAM dysplasia. This is not a real-time test during the surgical procedure and is very specific but not very sensitive for PLF, which may not contain CSF.[22]

In view of the difficulties of diagnosis, Weber et al.[21] suggest the policy of packing temporalis muscle around the oval and round windows in all suspected cases. This is based on the observation that packing does not seem to cause any significant complications (such as a subsequent conductive hearing loss) and he argues that it may be beneficial despite no confirmation of a PLF. In his series of 160 ears with suspected PLF there was a greater than 90% rate of stabilization or improvement in hearing in both PLF-positive and PLF-negative cases, though he acknowledges that in other series there is a similar outcome in nearly half of cases without packing.

High jugular bulb

A high jugular bulb (HJB) is usually asymptomatic and discovered as an incidental finding on otoscopy or during middle ear surgery. It can cause heavy bleeding from accidental puncture while lifting a tympanomeatal flap or even inserting a ventilation tube.

The jugular bulb can be defined as 'high' if it reaches the level of the inferior bony annulus and is often covered by thin bone or is dehiscent. In the presence of a plethoric mass within the tympanic cavity, the differential diagnosis will include HJB, aberrant ICA, a PSA and a glomus tympanicum tumour.

An HJB can be associated with hearing loss. If it includes a medial portion impinging on the cochlear or vestibular aqueduct, a connection with vestibular symptoms and a sensorineural hearing loss has been suggested. There may be a more direct association with a conductive hearing[23] loss due to interference with the ossicles, contact with the tympanic membrane and obstruction of the round window niche.

Major surgery to occlude or reroute an HJB is unlikely to be justified by symptoms alone, though there are occasional reports of intrusive pulsatile tinnitus associated with an HJB. It is possible to consider endovascular occlusion in the rare case of persistent haemorrhage, when tympanic cavity surgery is contraindicated.[24]

Aberrant internal carotid artery

This may be associated with other vascular abnormalities such as a PSA and likewise present as a vascular middle ear mass. Associated symptoms include pulsatile tinnitus, which may be objective, and hearing loss. In approximately 20% of cases it is bilateral.[25]

An aberrant ICA is an important differential diagnosis of a glomus tympanicum tumour, which can be resolved by CT scanning. Brisk bleeding, hemiparesis, aphasia, deafness, Horner syndrome and intractable vertigo may result if the vessel is unintentionally injured.[25]

BEST CLINICAL PRACTICE

- ✓ Unless deafness is bilateral, management can be conservative.
- ✓ If there is bilateral hearing loss, auditory rehabilitation will be required.
- ✓ Surgery is difficult with uncertain outcomes and best considered only by those with specific training and experience.
- ✓ Surgery may be best deferred until children can participate in the process of informed consent.

FUTURE RESEARCH

- ➤ The incidence, aetiology and pathogenesis of congenital ossicular abnormalities is poorly understood.
- ➤ The role of otoendoscopy in the diagnosis and management of these conditions needs to be better defined.
- ➤ Developments in middle ear implantation may render corrective surgery almost redundant.

KEY POINTS

- Congenital abnormalities of the middle ear may occur in association with major malformations such as microtia.
- Isolated malformations are rare but include anomalies of the ossicular chain and the middle ear vasculature.
- Diagnostic delay is common. Deafness due to ossicular pathology is often misdiagnosed as otitis media with effusion. It is not unusual for children to have repeated ventilation tubes before the correct diagnosis is made.

CHAPTER 13

OTITIS MEDIA WITH EFFUSION

Peter J. Robb and Ian Williamson

SEARCH STRATEGY

Data in this chapter may be updated by searches in The Cochrane Library, Medline, Google Scholar and PubMed, using the keywords: adenoid, adenoidectomy, biofilm infection, gastro-oesophageal reflux, otitis media, otitis media with effusion, ventilation tubes. References from selected articles were reviewed after reading the abstract and included where relevant.

DEFINITION

Otitis media with effusion (OME) is the accumulation of mucus within the middle ear and sometimes the mastoid air cell system. Persistence of the fluid for the condition to be described as chronic is normally taken as 3 months or longer.[1] In children, OME may present with hearing loss, but also delayed speech and language development, poor social behaviour and, in younger children, difficulties with balance. There is sometimes a clearly defined history of preceding respiratory tract infection and otalgia with an episode of acute otitis media. The condition is widely known among both doctors and the general public as 'glue ear'. Approximately 80% of all children will have had a single episode of OME before the age of 3 years and 40% will have three or more episodes.[2] In the USA, the cost of managing all forms of otitis media is estimated at US$5 billion (£3.2 bn, €3.7 bn) annually.[3]

When childhood OME is preceded by an episode of acute otitis media, however, this typically follows a viral upper respiratory tract infection, associated inflammation and infection of the adenoid, secondary bacterial infection with a cascade of inflammatory mediators,[4] upregulation of mucin genes and effusion from the middle ear mucosa. In many children with OME there is no clear history of acute otitis media. Research currently in progress indicates a genetic inheritance of susceptibility to OME, causing impaired middle ear oxygen metabolism.[5] It is likely that ventilating the middle ear establishes a higher oxygen tension in part, inhibiting bacterial biofilm activity.

AETIOLOGY AND PATHOGENESIS

Histology

The Eustachian tube and anterior mesotympanum are lined by ciliated, pseudostratified columnar respiratory epithelium. The mucosa contains both goblet cells and mucus-secreting glands.[6] Inflammation of the epithelium and production of a serous or mucus effusion results in OME. In established OME, the flat cuboidal middle ear mastoid mucosa may be replaced by thicker pseudostratified mucus-secreting epithelium with varying degrees of specialization, such as the development of cilia. Goblet cells are frequently present and sometimes mucus-secreting glands are formed. The ciliary lining would appear to be less efficient at moving the secretions into the nasopharynx than normal.[7] The submucosa is oedematous and inflamed with dilated blood vessels and an increased number of macrophages, plasma cells and lymphocytes.

CHARACTERISTICS OF THE EFFUSION

The effusion varies in composition but is predominantly made up of the glycoprotein mucin. Also present in the effusion are secretory immunoglobulin A (IgA), lysozyme, interleukins and other inflammatory cytokines. Rheological adhesiveness and poor mucociliary transportability are characteristics of the effusions and the behaviour of the mucosa predicting persistence of the effusion and the need for surgical drainage and middle ear ventilation.[8, 9]

Microbiology

Positive bacteriological cultures of middle ear aspirate of OME fluid in children (more than 2 months' duration) produces the anticipated range of respiratory bacteria, including *Streptococcus pneumoniae*, *Haemophilus influenzae* and *Branhamella* (*Moraxella*) *catarrhalis*.[10] However, 66% of the cultures were negative using traditional culture techniques, and no pathogens were cultured from fluid that had been present for at least 6 months. In contrast, using polymerase chain reaction techniques (PCR), 36% of middle ear mucosal biopsy specimens demonstrated intracellular *Streptococcus pneumoniae*.[11] The authors concluded this as important supporting evidence as a mechanism for bacterial persistence. Biofilms, which are communities of sessile bacteria, resistant to disruption and with a low metabolic rate, are embedded in a matrix of extracellular polymeric substances of their own synthesis. These communities may adhere to a foreign body or a mucosal surface with impaired host defence.[12] They are increasingly implicated in chronic inflammatory conditions such as OME. Biofilms were demonstrated in 92% of middle ear mucosal specimens of patients undergoing ventilation tube surgery for OME.[13] High-grade biofilm formation is also found on adenoid samples removed at surgery, supporting a role for adenoidal biofilm in the aetiology of OME. Adenoidal size is not correlated with biofilm formation, supporting the hypothesis that inflammation associated with the biofilm rather than adenoidal size per se blocking the Eustachian tube is the critical factor.[14] The contribution of biofilm formation in the middle ear and adenoid and the pathogenesis of OME is not yet completely understood, but it is likely that the biofilm is a secondary bacterial effect following viral respiratory tract infection, contributing to inflammation and mucus production. It is possible that those with a genetic defect of middle ear oxygen metabolism are predisposed to persistent OME with all its clinical manifestations.

Craniofacial abnormalities

OME occurs in nearly all infants and children with a cleft palate, and surgical repair of the cleft does not appear to reduce the incidence. The palatine muscles controlling Eustachian tube opening remain deficient through loss of decussating muscle fibres across the midline of the soft palate. In this group, OME has an incidence of at least 20% of 10-year-olds.[15] Children with a bifid uvula do not appear to have a higher incidence of OME[16] although, if adenoidectomy is combined with insertion of ventilation tubes, a sub-total removal should be performed under direct vision to reduce the potentially higher risk of velopharyngeal insufficiency.

It is unlikely that there is any correlation between dental malocclusion and OME.[17] While the incidence and persistence of OME in Down syndrome is well recognized, there is little evidence to clarify the factors contributing to the natural history of OME in those with Down syndrome.

Allergy

There is conflicting evidence on the importance of atopy and allergy in the pathogenesis of OME in childhood. In a validated questionnaire study of 89 children, with OME confirmed at the time of ventilation tube insertion, no difference in prevalence of allergic symptoms was found between the OME and reference group. Symptoms of nasal obstruction were significantly more prevalent, but this might represent adenoidal hyperplasia rather than allergic rhinitis.[18] In contrast, of 209 children with a history of OME extensively assessed in a specialist allergy clinic, 89% had evidence of allergic rhinitis, 36% had asthma and 24% eczema.[19] In addition to clinical history and examination, the assessment was based on nasal smears and skin prick testing, with blood eosinophil count and total immunoglobulin E (IgE) in a randomly selected subset. Such a study setting is subject to referral or spectrum bias. The worldwide prevalence of allergic rhinitis is 20%. The higher 89% figure reported in this study points towards a likely allergic component in many referred children with OME because of the strength of the association.[20] Furthermore, children with OME with a family history of allergy are more likely than controls to have a positive finding of rhinovirus in the middle ear cavity, indicating a link between viral respiratory tract infection and allergy predisposing to middle ear disease.[21]

Gastro-oesophageal reflux

The role of gastro-oesophageal reflux in the pathogenesis of OME in childhood is unclear, although it is known that, during swallowing, fluid can travel from the nasopharynx via the Eustachian tube into the middle ear. Gastro-oesophageal reflux is common in children, occurring in up to two-thirds of infants at 4 months of age, but decreasing thereafter.[22] Pepsin was first identified in middle ear effusions in 2002.[23] (Bile acids have also been identified in samples of middle ear fluid in children with OME.)[24] Biochemical analysis of middle ear fluid in OME suggest that pepsin is present in approximately 80% of samples at a level 1000 times higher than serum levels.[25] Mucosal damage is postulated to be mediated by the proteolytic activity of pepsin.

Pepsinogen immunoreactivity in adenoid tissue of children with OME has been found to be significantly higher than matched controls with no history of OME.[26] In this study, pepsinogen was detected in 84% of middle

ear effusions. *Helicobacter pylori*, confirmed by PCR assay, has been detected in middle ear effusions in 9/55 (16.3%).[27] An animal study concluded *H. pylori* did not per se cause a middle ear effusion, but rather contributed to the inflammatory process in the presence of middle ear fluid.[28] Gastro-oesophageal contamination of the middle ear appears not to correlate with symptomatic gastro-oesophageal reflux disease (GORD).[29]

The evidence in favour of a role for gastro-oesophageal reflux in the cause and/or persistence of OME is accumulating, but the relation between cause and effect, if any, is not fully understood. A systematic review of 242 studies (of which 15 met the inclusion criteria) concluded there is insufficient evidence to recommend antireflux treatment for otitis media with effusion.[30]

EPIDEMIOLOGY

The epidemiology of OME has been extensively studied in many countries. The studies include cohorts of children followed up at regular intervals for periods between birth and approximately 10 years of age. Most such studies are not designed or inadequately control for confounders (risk factors/effect modifiers). The background prevalence of OME is very high, making long-term effects difficult to evaluate with children frequently switching between having the condition and being clear of the condition. The prevalence of a condition is the number of true cases identified in a carefully estimated population (that might become cases) either over a fixed period or at any time point. Case ascertainment can be quite variable so tympanometry is recommended for larger studies (see 'Diagnosis' below for test characteristics). Such prevalence data are useful as an indicator of the potential clinical workload and the scale of the problem to children, their families and society. The incidence and remission rate of a condition measure the chances or rate of developing the condition and its clearance over a defined time frame respectively, which because of the chronic relapsing/remitting nature of the condition adds much value to the picture of the natural history, knowledge of which should help guide management decisions. In childhood OME, the two main determinants of the prevalence and incidence rates are the age of the child and the season of the year. When considering the evidence in this area there are many case-cohort level 2b studies to report from, but most of the larger well-conducted methodological studies are not recent.

Association with age

Zielhius et al.[31] reviewed a total of 23 studies that all used tympanometry as one of the diagnostic instruments to give age-specific prevalence rates up to 10 years of age. The background prevalence is bimodal with the first and largest peak found in approximately 20% of children aged 2 years. This is around the time when many children extend their social contacts, at playgroup or nursery school for example. Thereafter, the prevalence shows a dip with a second peak of approximately 16% in 5-year-olds, when most start attending a primary school. A study using a diagnostic algorithm of tympanometry combined with otoscopy in an attempt to improve precision, suggested that the early peak is most likely occurring around 1 year of age.[32] By the age of 8 years, the background prevalence in UK schoolchildren fell to 0–6% depending on time of year, whereas 5-year-olds had a higher season dependent range of 13–20%, 6-year-olds 8–13% and 7-year-olds 4–10%.[33]

Association with season of the year

In temperate climates, the effect of the season on the prevalence of OME has been recognized for many years, with around twice as many children being diagnosed with OME in the winter as in the summer months.[33–37] The most likely reasons for seasonal variation are the increased frequency of upper respiratory and ear infections in the winter, including the effects of seasonal influenza, and the greater chance of passing on infections between children because of the closer household contact in cold weather. If these factors are controlled for by analysis, however, the effect of season is no longer as evident,[38] but is demonstrated in other studies.[39, 40]

Little data exist for the effect of season from countries in non-temperate climates. The background prevalence of OME in Mediterranean children[41, 42] and subtropical countries[43, 44] does not appear to be very different from those in temperate countries but no independent effects for season are available. One study based in the northern tropical country of Vietnam showed increase in seasonal prevalence of OME from 3% to 11% when comparing the dry April with the December chilly rainy season.[45]

Risk factors for OME

The identification of the clinically most important risk factors is a key aspect of child health and clinical management because of the potential wide-scale benefit if these are able to be addressed, such as by strategic use of vaccines. Any identified risk factors cannot be assumed to apply equally to all age groups, for example breastfeeding effects may be greatest in the youngest cohorts. On *a priori* grounds, the risk factors for persistence of OME may well be different from the risk factors for its actual occurrence (incidence). Also one needs to consider the behavioural and clinical expression of the biological features including hearing impairments such as poor speech, or schoolwork that might be expected to relate more to how long the fluid has been present, and additional risk factors for 'disability' such as poor communicating styles.

When comparing evidence from risk factor studies it should be noted that potential factors are often inconsistently evaluated in the literature and heterogeneous, due to design issues, different populations, lack of agreement about what they are, and how to measure them uniformly and reliably. Often such studies have too few subjects with a particular characteristic to evaluate it reliably: for example, there are not many 5-year-old children who do

not go to school in the UK. A multivariate analysis can control for potential confounding variables. If low socioeconomic group is a mooted factor, for example, is it the small house, the number of siblings, the smoking, the junk food or the lack of a maternal university education and a car that makes the difference? It is unlikely to be all of these. Interim surgery in some risk factor cohort studies may complicate the analysis and interpretation, as it is clearly an important effect modifier of the outcome. It is deemed very likely that the risk factors for the occurrence of unilateral and bilateral OME will be the same. This premise has been experimentally confirmed by Engel et al.[40] That is why, in randomized clinical trials of children with OME, children rather than ears should be the unit of analysis for the primary outcome (because the ears are not independent variables).

Risk factors can be of interest in helping to understand why some individuals are more prone than others to suffer from a condition. Many journals prefer these presented as relative risk (RR) as easier to comprehend, although odds or hazard ratios may be used. In any specific individual, the number of risk factors present can be used as an approximate estimate of the risk of developing the condition. Usually, however, the relative risks for any single factor are only small (around two) and, to date, combinations of risk factors have not provided a sufficiently good or reliable guide for referral or interventions, although some factors may be modified.

Acute otitis media

In the age most studied, i.e. 0–2 years, recurrent episodes of acute otitis media (AOM) are frequent and this is likely to be the largest single group for developing persistent ear effusions. Each acute episode increases the reported odds ratio of developing OME by 12 (95% CI 6, 25) but this risk level no longer remains after 3 months.[46] Hence, the known risk factors for AOM, such as prematurity, frequent upper respiratory infections and non-breastfeeding, will apply in such clinical situations (OME preceded by AOM).[47] Studies of children in this age group that do not report the important frequency of AOM must also be considered less than optimal for clinical use in OME. There is no evidence that any medical management of AOM, including antibiotics, makes any difference to the chances of developing subsequent OME.[48]

Risk factors found in addition to AOM in a multivariate analysis confirm the increasing effect of age up to 2 years but also the effect of having siblings and a family history of them having OME.[38] Another study that otoscopically assessed family members of children with OME rather than just relying on historical reports found that 32% of siblings and 19% of parents were classified as otoscopically affected.[49] Other multivariate studies have suggested that, in addition to the number of siblings, attendance at day care with four or more other children up to 3.5 years of age can approximately double the risk (CI 1, 3).[39, 50] An international systematic review of risk factors found that the main risk factors for otitis media in populations were: attending day care, number of siblings, smoking, not breastfeeding, low birthweight and socioeconomic status.[51] Some of these factors are potentially modifiable (e.g. the number of children in day-care settings could be reduced to lessen this risk), but for most parents availability, convenience and cost are limiting determinants.

Genetic factors

In a same-sex twin/triplet prospective cohort study, Casselbrandt et al.[52] looked at sets where the zygosity was known. In children who had OME during the first 2 years of life, there was greater concordance in monozygotic sets in both the number and duration of OME episodes than in dizygotic sets. The magnitude of the effect of heredity in comparison to other risk factors for OME was not investigated. More recent work in mouse mutant models of chronic otitis media (COM) where hypoxia in microenvironments is known to be aetiologically important has demonstrated upregulation of hypoxia inducible factor (HIF) and vascular endothelial growth factor A (VEGFA).[53] This paves the way for targeted therapeutic interventions in future studies, although transferability of mouse-model findings to humans requires some caution and fuller evaluation.

Race

Whether the prevalence of OME is truly different in different races requires control for many other factors. When factors including socioeconomic group and child contacts are controlled for in a multivariate analysis, the prevalence in black children is no different from white children.[54] Chinese children may have a lower overall prevalence, but a multifactorial analysis has not been reported.[44]

Gender

Some multivariate studies report the risk of developing OME to be no different between boys and girls.[39, 40, 55] Some studies report a higher risk in boys[46, 49] and others a higher risk in girls.[38] It must be concluded that there is likely to be little difference, if any, in the background risk for boys compared to girls, with most epidemiological studies showing comparable base rates.

Smoking

For public health reasons, parental smoking has frequently been reported as a risk factor for the occurrence of OME. However, in one multivariate analysis when other factors had been controlled for, no effect of parental smoking was detected[40] but in another study it was found present for smokers of up to 20 cigarettes per day.[39] A large, more recent epidemiological study noted a temporal decline in consultations for otitis media, which was attributed to an increase in smoke-free households.[56]

Duration and recurrence of episodes

One large study of 1328 children aged 1–2 years showed the duration of episodes in individual ears was very skewed; the median duration of effusions was 3 months

or less, but the 95th percentile was at 12 months. Half of affected ears had resolved after 3 months. However, around 50% of the ears that resolved had a further episode.[57] What happens in individual infants rather than in ears has been well documented by Paradise et al.[54] in a large cohort (n = 2253) followed up from 2 months of age to 6, 12, 24 months of age, who found that 49%, 79% and 91% of infants respectively had had at least one episode of OME.

Hogan et al.[58] followed up 95 full-term infants monthly for 3 years. Overall, infants were twice as likely to develop unilateral as opposed to bilateral OME. One month later, in infants with a unilateral effusion, the majority (50%) had resolved, a minority (20%) had become bilateral and the other 30% remained unilateral. In those with bilateral effusions at the start, the majority (60%) remained bilateral 1 month later. In the others (40%), bilateral resolution was more frequent than unilateral resolution (in a ratio of 3:1).

An older cohort of 856 British children aged 5–8 years was screened three times a year (approximately every 4 months) for 3 successive years.[33] In a subsample of 67 ears with B tympanograms and with three consecutive screens, the resolution rates (to a non-B) at 4, 8 and 12 months were 52%, 78% and 91% respectively. The overall recurrence rate for this community study was quite low at 7%. A more detailed monthly study of 7-year-old Danish pupils (n = 387) reported the mean overall duration of an ear episode to be 1.8 months with 12% lasting more than 6 months.[59] Ears first diagnosed to have OME between September and February persisted longer than those first diagnosed between March and August.

Risk factors for persistence

Three studies have been identified that have followed up children to identify risk factors that might be used to predict those who are more likely to have persistent bilateral OME. One study was carried out in primary care and followed up children of 6 months or older for 3 months.[60] Another study was of children aged between 3 and 7 years referred from primary care with suspected OME and seen at secondary care on average 13 weeks later.[61] The third study was of children of the same age identified at secondary care to have bilateral OME with an associated hearing impairment in both ears of at least 20 dB hearing loss. These children were followed up for 3 months to identify those in whom the OME persisted bilaterally with the same degree of impairment.[62–64]

In these three studies, which all followed up the children for 3 months, the persistence rates of bilateral OME were 56%, 35% and 51% respectively. All studies identified the second half of the year (July–December) as a major risk factor, with odds ratios of between two and three. In primary care, whether a child has frequent or upper respiratory symptoms at the time of assessment is also an important determinant of persistence. In secondary care, the degree of associated hearing impairment predicted persistence. The only factor that might have had an influence and has the potential to be modified was whether the mother smoked, and this was a significant multivariate factor in the secondary care study.[61] In all three studies, the magnitude of the effect of any factor singly or in combination was insufficient to predict with reasonable certainty those likely to persist or resolve.

Clinical summary of best epidemiological evidence

The prevalence of OME in childhood is age-dependent, with two peaks in the distribution, one centred around 1–2 years of age and the other around 3–7 years of age.

In temperate countries, twice as many children have OME in the winter as in the summer. The increased frequency of upper respiratory infections and close contact with other children during the winter months contribute to this association.

Under 3 years of age, episodes of AOM, contact with other children and heredity are factors that increase the risk of occurrence. Unilateral OME is twice as common as bilateral OME. Those with a propensity to develop OME have more frequent episodes rather than longer episodes. Bilateral OME is more likely to persist than unilateral OME. In primary care, children with bilateral OME and a history of upper respiratory infections are more likely to persist. In secondary care, children with bilateral OME seen in the second half of the year (July–December) with a hearing impairment of 30 dB HL in both ears are more likely to persist.

None of the factors for persistence singly or in combination are sufficient to negate a requirement for a 3-month period of active monitoring before considering surgery.[65]

DIAGNOSIS

History

Parental recognition of hearing loss in their child is perhaps surprisingly only poorly correlated with OME. In a population-based study of 117 children with OME and 159 controls, parental suspicion of their child's hearing loss in the affected group was only 19.7%.[66] Furthermore, parents of children with OME tend to underestimate the severity of the hearing loss and overestimate their child's quality of life when assessed with the validated OM-6 questionnaire.[67] When parents were reassessed after surgical treatment of their child's OME, there was a significant response-shift bias for both hearing loss and quality of life. Indeed, many parents report concerns other than hearing loss, including poor speech and language development and signs of difficulties with balance. When balance was formally tested, one study reported improvement in balance with practice, but less so in those children with OME until after ventilation tube insertion.[68] In a case-control study, the post-surgery treatment group had a statistically significant decrease in sway velocity compared to the control group.[69] Children attending day care or nursery also may cause their carers or teachers concern, because of inattention and behavioural problems.[70] Difficulty taking part in group activities due to the hearing loss associated

with OME actually reflects an underlying impaired ability to process speech in noise which is more noticeable in this context than in one-to-one situations with primary carers.[71]

Taking a history, it is important to confirm a normal pregnancy, delivery and neonatal period and that neonatal hearing screening was performed and reported as normal. A very small number of children may pass neonatal hearing screening and have or develop sensorineural hearing loss during early childhood. It is important to be aware of the possibility of OME coexisting with a mixed hearing loss. Children with comorbidities (e.g. Down syndrome, cleft palate) are more commonly affected by OME, and this is usually more persistent.

Examination

OTOSCOPY

In some children, otoscopy may not be possible, either because the child is unable to cooperate or because the view is obscured by wax. In primary care, sodium bicarbonate or olive oil eardrops are often prescribed to soften and encourage dispersal of the wax. In second-tier community clinics and in secondary care, tympanometry and audiometry will usually provide sufficient additional information on the level of hearing loss, with or without wax obscuring the view of the tympanic membrane (**Figure 13.1**).

Otomicroscopy

In a study of 81 children (155 ears) using otomicroscopy with myringotomy under local anaesthesia as the reference standard, otomicroscopy showed better diagnostic agreement with myringotomy than otoscopy or tympanometry.[72] While not applicable to the outpatient clinic setting, intra-operative otomicroscopy performed by a specialist otolaryngologist in the anaesthetized child prior to myringotomy achieves greater diagnostic accuracy than pneumatic otoscopy and tympanometry. The overall accuracy of otomicroscopy was 94.1%.[73]

Figure 13.1 Normal right tympanic membrane. (Image courtesy of Mr Michael Saunders.)

Pneumatic otoscopy

When performed by trained specialists, the sensitivity of pneumatic otoscopy ranges from 85% to 93% and its specificity from 71% to 89%. However, these calculations omitted up to 20% of the children in whom pneumatic otoscopy was not possible.[74] Including these children alters the sensitivities and specificities dramatically. The sensitivity and specificity of pneumatic otoscopy, even where practicable, would be markedly poorer in practitioners whose skills have not been validated.[75] In contemporary practice, many clinicians will rely on a combination of otoscopy and tympanometry when assessing small children.

TUNING FORK TESTS

In a study of 58 children, aged between 2 and 11 years, the Rinne and Weber tuning fork tests poorly predicted conductive hearing loss in children with OME compared with pure tone audiometry. The results were independent of the child's age.[76] Tuning for tests should not be relied on to assess conductive hearing loss.[77]

FREE-FIELD VOICE TESTING

In primary care, audiometry is seldom available, particularly for younger children. In children over the age of 3 years, the sensitivity of modifications of the voice test administered by experienced examiners (e.g. use of pictures to point at or two-syllable words) is 80–96% and the specificity is 90–98%.[78] However, these outcomes are unlikely to be achieved when carried out by less experienced examiners in a primary-care setting.

Investigations

TYMPANOMETRY

For more than 30 years, tympanometry using an automated impedance meter (see Chapter 51, Psychoacoustic audiometry) has been widely available as a method of detecting OME. While an acoustic seal is sometimes difficult to achieve, bilateral tympanograms are generally obtainable in 98% of children between the ages of 3.5 and 7 years,[79] in 90–94% of infants 2–11 months of age[80] and 78–88% of infants 12–24 months of age.[81]

A modification of the Jerger classification is the most commonly used in clinical practice.[31, 82] This uses compliance and pressure as the numerical parameters, presented visually as a compliance curve (**Figure 13.2**).

Comparing the finding of middle ear fluid at the time of myringotomy, soon after tympanometry, a type B tympanogram is frequently associated with OME; a type A is infrequently associated with OME and a type C falls in between.[84] This study did not, however, subdivide type C tympanograms as type C_1 or C_2.

Overall, a number of level 1 evidence studies conclude that a type B tympanogram compared with all other types of tympanogram has a sensitivity of between 56% and 73% and a specificity of between 50% and 98% in detecting OME confirmed at the time of myringotomy.[84–86] Compared with

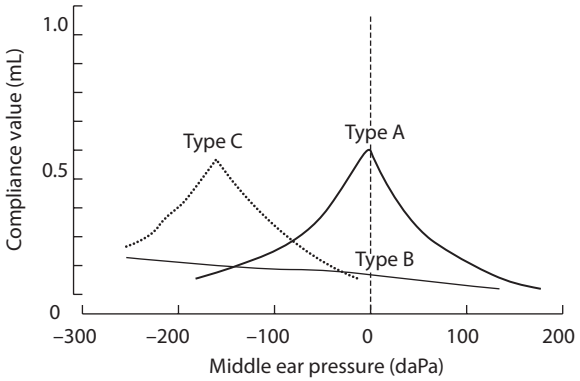

Figure 13.2 Tympanogram trace types.[83] A, peak between +200 and –99daPa; C, peak between -100 and -399daPa (further subdivided into C1, peak between –100 and –199daPa; C2, peak between –200 and –399 daPa); B, no observable peak between +200 and –600 daPa (Image courtesy of Mr Michael Saunders.)

all other types, a type B plus C_2 has a greater sensitivity of between 73% and 99%, and a specificity of between 40% and 74%.[87–90] The reasons for such a wide range of values are unclear and can be only partly explained by the differing proportion of ears with OME (sample bias). When nitrous oxide is omitted from general anaesthesia at the time of myringotomy (excluding the risk of a 'false dry tap'), the sensitivity and specificity of a Jerger type B trace predicting middle ear fluid is 0.73 and 0.84 respectively.[91]

Tympanoscopes

Automated, hand-held tympanoscopes (screening tympanometers) have the advantages of portability and lower cost and are particularly suited for primary care. In a primary care setting, when this equipment is used by trained operators,[92, 93] and a type B tympanogram is classified with a type C_2 tympanogram, the sensitivity and specificity (100% and 75%) is comparable to conventional impedance bridge tympanometry.[94, 95]

TYMPANOMETRY IN COMBINATION WITH OTOSCOPY

The diagnostic predictability of otoscopy and tympanometry, when in agreement, can be referenced against the findings at myringotomy.[96] When otoscopy suggests OME and is associated with a type B tympanogram, the combined sensitivity is 98%. When otoscopy suggests no OME and is combined with a type A tympanogram, the specificity is 98%. However, in this study the findings were in agreement in only 44% of ears. In the 56% where the results were not in agreement, another indicator of OME such as audiometry would be required to confirm the diagnosis. A combined otoscopy and tympanometry sensitivity and specificity were calculated for those otoscopy and tympanometry determinations in agreement, revealing both sensitivity and specificity above 90%.

ACOUSTIC REFLEXES

Measuring the acoustic reflexes in association with classification of tympanometry as peaked/non-peaked substantially lowered its specificity while adding little to the sensitivity, and it is therefore not recommended.[97, 98]

AUDIOMETRY

Audiometric assessment is mandatory for all children referred to secondary care with a suspected hearing impairment. While all children in the UK will have an objective neonatal hearing assessment, this does not guarantee continuing, normal hearing throughout childhood because some will develop sensorineural hearing loss. If a hearing loss is diagnosed in the absence of OME, this should be pursued with further hearing assessment, including bone-conduction thresholds and objective electrical response audiometry. Approximately 1% of children will have a previously undiagnosed congenital, sensorineural hearing loss[97] and a smaller number a postnatal hearing loss from *in utero* infection (e.g. cytomegalovirus).

Conventional air and bone conduction testing is the preferred method as it tests each ear separately and can quantify any conductive component present. In children over 3.5 years of age, air and bone conduction thresholds are obtainable in the majority of children (95% and 92% respectively) on the first occasion. Age, rather than the method of audiometry, is the main determinant of whether thresholds are obtainable. Even if the child's concentration is poor, the results on average are only 5 dB poorer and can still be used to guide management.[99]

Evidence from a small study of 31 children compared high-frequency hearing between 14 who had experienced no more than three episodes of bilateral OME and those who had experienced at least four episodes. There was an increase in hearing thresholds with increasing frequency, higher than those normally clinically tested (9 kHz to 18 kHz) and poorer high-frequency hearing in the group who had a history of four or more episodes of OME.[100]

Air–bone gap

The presence of an air–bone gap of at least 10 dB is a poor predictor of concurrent OME. It was only when the air–bone gap was greater than 30 dB that the dry tap rate reduced to 4% (1 of 27).[101]

Carhart notch in the bone-conduction thresholds

As OME is a conductive hearing loss, it is associated with a Carhart notch in the bone-conduction thresholds around 2 kHz. (By definition, the notch has to be 10 dB or greater between 0.5 kHz and 4 kHz as any lesser dips could be due to test/retest error.) Accurate bone-conduction thresholds are required and, in younger children, this may not be possible. In children older than the typical age group for OME, a Carhart notch was present in 48% of children with OME whose mean age was 9 years.[102] In those able to perform bone-conduction audiometry, the positive predictive value of a Carhart notch in diagnosing fluid at myringotomy was 97% and the negative predictive value was 87%.[103]

Diagnosis and management of OME

Confirmation of the diagnosis of childhood OME is based on a combination of otoscopy, tympanometry and audiometry. Otoscopy should be attempted in all children, not just to diagnose OME but also to confirm or exclude other ear pathology (Figure 13.3). Pneumatic otoscopy may be of added value where there is uncertainty, but it is limited in predictive value by the experience of the examiner and the cooperation of the child.

In a general secondary care setting, where audiological testing of younger children is not available, children under the age of 4 years should be referred to a community paediatric audiology (second tier) clinic for age-appropriate hearing assessment, combined with tympanometry. Children of 4 years of age and above, in the absence of cognitive or behavioural comorbidity, can be assessed in a general hospital paediatric ENT clinic, with both audiometry and clinical assessment on the same visit. When OME is confirmed, active monitoring of hearing over a 3-month period is recommended.[104] The benchmark for hearing loss due to bilateral OME is hearing in the better ear of 25–30 dB HL or worse, averaged at 0.5, 1, 2 and 4 kHz. Tympanometry will typically demonstrate probability of effusion in cases of reduced middle ear compliance, with Jerger type B or C_2 traces.

As well as applying strict audiometric criteria, it is also important to make a child-centred assessment as to how the child's hearing loss may affect their quality of life. Where the impact of the hearing loss, although less than 25–30 dB HL is judged to have a significant impact on the child's development, social skills or educational attainment, more active management is appropriate.

Having excluded a sensorineural hearing loss with audiometry, it is reasonable thereafter to use tympanometry alone to identify those children with persistent hearing impairment due to OME. Taking 25 dB HL in the better-hearing ear as the level requiring detection, limiting audiometry to those with a bilateral type B reduces audiology workload by 50% but detects 90% of such impaired children. Limiting audiometry to those with bilateral type B or C_2 tympanograms reduces the workload to 69% of the sample yet detects 95% of the children with hearing impairment due to OME.[79]

OUTCOMES OF CHILDHOOD OME

Natural history

The natural history is very important, as outlined above, and can help guide management in both primary and secondary care. Hogan found that the effusions in children under 3 years of age with a propensity to have bilateral OME lasted on average 10 weeks, albeit the children were likely to have a further episode within 11 weeks.[58]

The UK MRC (Medical Research Council) TARGET (Trial of Alternative Regimens in Glue Ear Treatment) study is also an invaluable source of natural history information in those children referred to secondary care aged between 3 and 7 years of age. A total of 3831 children of this age were referred because of suspected OME. The techniques for correctly diagnosing and detecting OME across primary care are currently less than adequate, with reliance predominantly based on subjective histories. When screened at the trial clinic, only 34% satisfied the criterion for further study of having bilateral OME associated with a hearing impairment of at least 20 dB HL in both ears.[62–64] This cohort underwent a 12-week watchful waiting period, following which 49% of children no longer met the bilateral OME hearing criterion, i.e. only 51% of the hospital cohort persisted. At that stage, children with persistent OME were randomized and, in those who had non-specific medical management, only 49% remained persistent 3 months later.[65] In summary, children referred into the TARGET study waited on average 13 weeks to be seen, underwent a watchful waiting period of 3 months and then waited a further 3 months for surgery, by which time in 92% the hearing impairment associated with their OME had resolved. Thus, even in secondary care, the vast majority of children with bilateral OME resolve spontaneously over a 9-month period, although the OME might recur.

OTOPATHOLOGY

Addressing the natural history of OME and possible progression to cholesteatoma, the best evidence comes from a large study of 964 children, screened for OME every 3 months between the ages of 2 and 4 years. The children were subsequently re-examined with otoscopy at between 7 and 8 years of age.[106]

The findings indicate that attic retractions are a disease effect of OME, with an incidence of approximately 14% in the most severely affected children (Figure 13.4). The proportion of these retractions that progress to cholesteatoma remains unknown. There is no evidence that the risk of attic retraction is altered by the insertion of ventilation tubes. Tympanosclerosis and atrophy of the pars tensa are also disease effects of OME. The risk of these is increased by the insertion of ventilation tubes to more than 45% and approximately 70% respectively. Long-term pars

Figure 13.4 Attic retraction. (Image courtesy of Mr Michael Saunders.)

tensa retractions (approximately 15%) are more likely to be due to insertion of ventilation tubes than by the disease process itself.

CONDUCTIVE HEARING IMPAIRMENT

There is a widely variable hearing loss due to OME. In a series of 385 children aged between 2 and 11 years with bilateral OME confirmed by a diagnostic algorithm including pneumatic otoscopy, tympanometry and reflexes, the hearing loss in the better-hearing ear varied from 0–4 dB HL to 50–54 dB HL.[107]

Overall, the mean threshold in the better ear was 21 dB HL (s.d. 10). In 54% of those with bilateral OME the pure-tone average in the better ear was better than 20 dB HL.[107] The mean threshold in the poorer-hearing ears was 31 dB HL (s.d. 13). The speech reception or speech awareness thresholds in infants in this study were of a similar distribution. This might suggest that many children with bilateral OME in this study had an insufficient hearing impairment to cause 'significant' disability warranting such intervention, although significance remains difficult to define. In the same study, the authors describe a group of children with unilateral OME. In these children, the mean threshold in the better ear was 11 dB HL (s.d. 7) and 23 dB HL (s.d. 10) in the poorer ear, indicating these are a potentially significant group who may experience hearing disadvantage on occasions.

While there is no predictable difference in the hearing levels in ears from a serous effusion compared with those with a mucoid effusion,[108] those children with recurrent OME have an effusion with a different rheological profile, with fluid that has higher frictional adhesion.[8]

Sensorineural hearing impairment

There is no high-level evidence indicating that OME is associated with sensorineural hearing impairment in the short term.[109] However, the previously noted study[100] described sensorineural hearing loss above the clinically tested frequency range (>9 kHz) in children with recurrent episodes of OME. High-frequency sensorineural damage above 8 kHz has also been reported in a case series of children with OME who had been operated on and followed up for between 3 and 5 years.[110]

Long-term hearing impairment

In children followed from birth to 18 years of age, those who had otitis media (both acute and OME) produced air-conduction thresholds 4 dB HL poorer on average and bone-conduction thresholds poorer on average by 2 dB than those who had not had otitis media.[111] In this clinically heterogeneous group, it is not possible to know if the poorer thresholds were the result of infection, OME or surgical intervention.

SPEECH AND LANGUAGE

Normal childhood speech and language development is a multifactorial process, dependent on many factors including the age of the child, the ethnic background and verbal communication at home, particularly from the primary carer. Hearing impairment, including that from OME, is likely to impede normal speech and language development. Assessment of speech and language is complicated by it having many components, including speech reception, speech and sound production, expressive language and cognitive understanding.

In comparison to the profound effect on speech and language development a severe sensorineural hearing loss would be expected to produce, the mild to moderate conductive hearing loss associated with OME in the first 2–3 years of life should result in a much smaller effect. In a meta-analysis of 14 studies, the authors concluded that the impact of OME in early childhood on later speech and language development was very small, and of uncertain clinical relevance.[112] However, the authors cautioned generalizing the findings, instead recommending child-centred individual management in the context of other variables, including attention to language skills, development and the general supportiveness of the child's environment. Prospective cohort studies suggest an impact of otitis media, related to the number of days with bilateral fluid during the first 2–3 years of life. However, follow-up of these children when they are 7–8 years of age suggests that, by then, the children have caught up with their non-affected peers.[113] Overall, while the data suggest a mild effect on speech production in early childhood,[114–116] evidence looking at receptive language, using speech reception in noise (SiN) rather than pure tone audiometry, shows that 40% of children with the poorest pre-treatment SiN scores achieved high benefit from insertion of ventilation tubes. The authors concluded that SiN is a better tool than pure tone audiometry to predict benefit from surgical intervention. There appear to be small but significant long-term effects on sound discrimination in children with a history of OME.[117, 118] If there are measurable lasting effects, from current evidence these seem to predominantly affect receptive language. Treating OME in very young children appears to have no significant effect on speech and language development in the short term.[119, 120]

COGNITION

The influence of OME as one of many interrelated variables affecting a child's intellectual development is difficult to determine. Cohorts of children can be grouped as to how much OME they have had and this is correlated to a particular outcome, having controlled for demographic and environmental factors. The effect of OME as an independent factor for academic development is probably small compared with the more influential demographic, social and economic factors. If there is an effect, this has been reported as generally small.[118, 121] While these studies conclude that any negative effect has disappeared by the age of 7–8 years, a birth cohort of 200 was reviewed as older children, during their teens. A history of OME in early childhood was associated with a deleterious effect on reading ability.[122] A further study[123] reviewing a larger cohort of the same group[124] concluded a lower IQ in the OME group, after adjustments for covariates, persisting at least until the age of 13 years.

BEHAVIOUR

Behaviour can be assessed using questionnaire reporting by parents or teachers. These give a global behaviour measure and can also score the various components of behaviour. The widely used Rutter Children's Behaviour Questionnaire[125] is subdivided into antisocial, neurotic, hyperactive and inattentive behaviour scores.

In a randomized, controlled trial, 55% of 3-year-old children with bilateral, 3-month persistent OME had abnormal overall Rutter scores, compared with 10–15% of unselected 3-year-olds.[126] There is also evidence that, even when a child with a history of early OME has reached the age of 13 years, they performed less well than non-OME children for neurotic and inattention traits. By 15 years of age, the OME group scored less well in the total behaviour score and specifically for inattentive and hyperactive behaviour.[122, 123]

BALANCE

While OME is one of the most common causes of balance disturbances in young children,[127] only about 30% of parents of children with OME report that they are concerned about their child's balance. When formally tested, 61% of children with OME have objectively defective motor proficiency; these symptoms resolve following insertion of ventilation tubes.[126, 127]

QUALITY OF LIFE

Quality of life (QOL) is a multidimensional concept reflecting general valuation of health states, also important as a child- or parent-centred measure of outcome in routine contexts. Only relatively recently have specific ear-related QOL measures been developed. The MRC Multi-centre Otitis media Study Group has produced the OM8-30 functional health status measure, which has been impartially evaluated, with favourable recommendation[128] and mapped onto generic QOL.[129] For routine patient-reported outcome measure (PROM) applications emphasizing QOL, a short-form easy-to-use measure, the OMQ-14, has recently been developed from the OM8-30. This uses two databases, from UK secondary[130] and primary[131] care trial cohorts, to define the 14 items from OM8-30 best reflecting QOL. Facets covered by the OMQ-14 questions include four main profile areas: (i) recurrent AOM, (ii) reported hearing difficulties, (iii) behaviour and parental QOL, and (iv) speech and language. Clinical research currently being performed using these measures is suggesting that such estimates of child- and parent-centered outcomes in 'the real world' are of considerable practical use. This is partly because hearing level, although an important assessment and outcome, demonstrates only low correlation with QOL. Short questionnaire measures have great potential to become a useful routine aspect of individual clinical assessment, alongside their current research use as an evaluation of interventions for OME.[132]

MANAGEMENT

Counselling and hearing tactics

Parents of children with OME are often misinformed about many aspects of the condition. In particular, they can have over-pessimistic views about its severity and be over-optimistic about the merits of surgery. At their first visit to the general practitioner or the specialist, time has to be spent explaining that, in general, OME is a benign condition with a high spontaneous recovery rate with no serious long-term sequelae. In most children, the main concern will be the hearing. It should be explained to the parents that the impairment associated with OME is very variable in degree and duration and mild or moderate at most.

It is important that all parents of children with OME receive appropriate general counselling about the natural history and relative benign nature of the condition. Those in contact with the child, including any minder or teacher, should be made aware that hearing-related disability can be minimized by adopting hearing tactics, including the following:

- Get the child's attention before starting to talk.
- Reduce the background noise as much as possible (e.g. turn off the television).
- Face the child so that they can see you talk to encourage lip reading.
- Speak in a normal voice in volume, speed and emphasis, as close as possible to the child.

Leaflets such as *Glue ear: A guide for parents* offered to parents could reinforce the above messages.[133]

Medical management

Medical management would potentially be of greatest benefit if it could speed the resolution of an episode of OME. Hence, randomized controlled trials carried out in

primary care settings would be those most appropriate to consider using resolution of OME as the outcome. Such studies need to define their target populations to exclude non-cases, etc. Some trials followed up children for just 1–2 weeks after therapy. However, if any treatment is effective after 1–2 weeks, then follow-up for the recommended watchful waiting period of 12 weeks is necessary to see if it is of benefit in the longer term, and might be used to reduce the proportion of children being considered for surgery.

NASAL TOPICAL STEROIDS

A Cochrane systematic review[134] identified several studies of topical nasal or oral steroids versus placebo.[131, 135, 136] The review, which included a sizeable UK study of nasal steroids versus placebo from UK primary care, concluded that there is evidence for no benefit from topical intranasal steroids.

SYSTEMIC STEROIDS

Considerable concern has been expressed about the use of oral steroids being given to children for a non-life-threatening and spontaneously resolving condition. Consequently, such treatment would have to be highly effective in the long term before it could be recommended. The review that included 12 studies in total and 945 patients[134] did, however, find some evidence to suggest that oral steroids are effective in the short term (2 weeks), and when combined with antibiotics.[137, 138] Systemic steroids cannot be recommended at present for childhood OME.[139]

ANTIBIOTICS

A Cochrane review based on 23 trials mostly from secondary care and 3027 subjects has suggested that antibiotics are unlikely to be beneficial.[140] There was evidence to show that antibiotics had no statistically significant benefit in the short term. Because trials were very heterogeneous, meta-analysis was not attempted. In the longer term there appeared to be slight benefit from use of antibiotics but there are some concerns about the generalizability of these data, and the disadvantages of antibiotics: rashes, diarrhoea, antibiotic-associated colitis, anaphylaxis, thrush and antibiotic resistance are increasingly well known, making them unsuitable for longer-term use. In particular, the Chief Medical Officer for England and Wales has highlighted antibiotic resistance as a major public threat to health.

NASAL DECONGESTANTS

A systematic review and meta-analysis of four trials (n = 1202) found that antihistamine/decongestants had no significant effect on the resolution rate of OME.[141] Nasal decongestants are not recommended for use in childhood OME.

MUCOLYTICS

A systematic review of six randomized controlled trials of S-carboxymethylcysteine published before 1993 could not demonstrate that they had an effect.[142] A later trial also showed no significant effect.[143] Because of a non-significant trend for increased benefit in these small, biased trials, a larger well-designed study is merited.

Other non-surgical approaches

AUTOINFLATION

A systematic review of autoinflation for the treatment of glue ear in children identified eight studies with 702 participants.[144] Pooled estimates found non-significant improvement in tympanometry at less than 1 month (relative risk of improvement (RRI) 1.47, 95% CI 0.69–3.13) and non-significant improvement at more than 1 month (RRI 1.22, 95% CI 1.00–1.49). A composite measure of tympanometry with audiometry showed a significant improvement at more than 1 month (RRI 1.74, 95% CI 1.22–2.50). Because of the low cost and absence of reported adverse effects, it was concluded that autoinflation was worth considering while awaiting natural resolution, and that primary care was a good setting for further studies. Some concerns have been raised though about the age at which the method can be performed reliably in children, and this also requires further evaluation. Currently autoinflation appears the most promising non-surgical management to augment active monitoring (watchful waiting).

HOMEOPATHY

No randomized controlled trials have been identified. A small, non-blinded study showed homeopathy to be of no benefit.[145]

Surgery

MYRINGOTOMY AND INSERTION OF VENTILATION TUBES

Myringotomy with aspiration of middle ear fluid but without insertion of a ventilation tube (grommet, tympanostomy tube) is ineffective surgical management of OME.[146] The incision closes within a few days and the effusion usually recurs.

Ventilation tubes of different materials are available, although in the UK, Teflon® grommets are typically used. Titanium-, gold- or silver oxide-coated ventilation tubes are intended to inhibit biofilm formation, although *in vitro* evidence indicates this is only the case if the material is coated with antibiotic.[147] Using scanning electron microscopy, some biomaterials, such as ionized, processed silicone, appear more resistant to biofilm formation, reducing the incidence of plugging of the tube and post-operative otorrhoea.[148]

Standard pattern ventilation tubes (e.g. Shepard, Shah – **Figure 13.5**) stay *in situ* for a shorter period than longer-term T-tube designs (**Figure 13.6**), but the longer a tube stays *in situ*, the higher the chance of complications, including plugging of the lumen, infection, thinning and collapse of the tympanic membrane with possible retraction and permanent perforation.[149] Up to 55% of Shepard

Figure 13.5 Right tympanic membrane Shah grommet *in situ*. (Image courtesy of Mr Michael Saunders.)

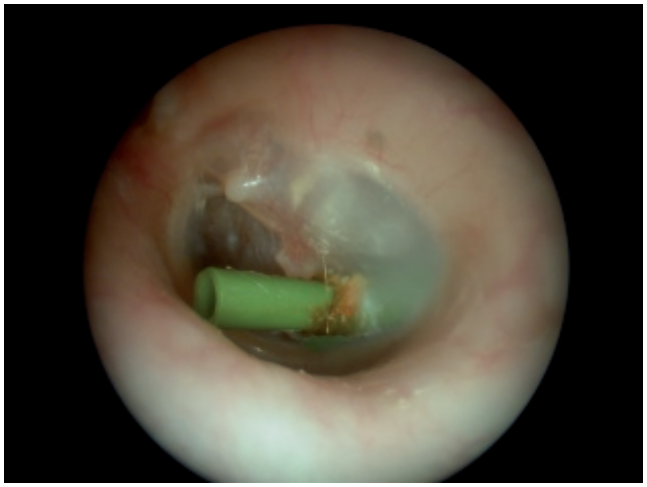

Figure 13.6 Right tympanic membrane T-tube *in situ*. (Image courtesy of Mr Michael Saunders.)

ventilation tubes have extruded within 6 months of insertion;[149, 150] in the same period, approximately 10% of T-tubes will have been extruded.[148]

In the future, both biofilm formation with infective complications and persistent perforation may be reduced or abolished by a currently experimental biodegradable, absorbable ventilation tube manufactured from poly-bis (ethylanate) phosphazene.[151]

Surgical technique

Site To maximize the duration of placement and minimize damage or perforation, the preferred insertion site of the ventilation tube is anteroinferior through a circumferential or radial incision. Insertion of the ventilation tube posterosuperiorly is not recommended because of the risk of damaging the ossicular chain. The ventilation tube inserted via a radial or circumferential incision does not influence the extrusion rate.[152] Placement of the grommet anteroinferiorly compared with placement posteroinferiorly lengthens the time a Shepard ventilation tube remains *in situ* (80% versus 45% at 6 months and 30% versus 15% at 12 months).[153] A tube placed anteriorly is also associated with a reduced but non-significant reduction in persistent perforation compared to a tube placed posteriorly in the tympanic membrane (1.8% versus 3.7%).[153]

Surgical aspiration While usual practice is to aspirate middle ear fluid through the myringotomy prior to insertion of ventilation tubes, there is no evidence to support this. Hearing levels 3 months following insertion of a ventilation tube were the same independent of aspiration.[155, 156] A literature review of the topic concluded aspiration produced increased rates of tympanosclerosis, secondary to trauma and bleeding of the tympanic membrane. Noise from persistent aspiration may lead to permanent noise-induced hearing loss.[157] Aspiration causing bleeding from the tympanic membrane may encourage subsequent biofilm infection of the ventilation tube.[158]

Topical preparations Ear drops can be used at the time of insertion of ventilation tubes to reduce the risk of tube blockage with blood and mucus, and to minimize local infection during the early post-operative period (see 'Complications of ventilation tubes' below).

ADENOIDECTOMY

Surgical techniques

In the UK, blind curettage adenoidectomy continues to be the most used technique. Digital palpation and blind curettage is used in 79.2% of cases, while only 8.1% use suction coagulation under direct vision.[159] It is surprising that curettage remains popular suffering the disadvantages of a blind procedure with unpredictable bleeding, poor access to choanal adenoid and risk of trauma to the Eustachian cushions. In contrast, suction diathermy affords direct vision with minimal blood loss[160] (mean 4 mL versus 50 ml L), haemostasis and negligible risk of post-operative haemorrhage.[161] Suction diathermy is also effective in performing partial adenoidectomy, leaving a ridge of adenoidal tissue at the inferior part of the nasopharynx, reducing the risk of velopharyngeal insufficiency in those children where this is likely after removal of the adenoid.[162] Other direct vision techniques include Coblation® and microdebrider, which have the disadvantage of high unit cost for adenoidectomy alone. KTP laser is associated with a high risk of nasopharyngeal stenosis,[163] which has not been reported using gold laser for adenoidectomy.[164] All single-use instrument techniques have the advantage of abolishing the potential risk of infection transmission[165] (see Chapter 26, The adenoid and adenoidectomy).

SURGICAL OUTCOMES

Hearing outcomes of ventilation tube insertion

The Cochrane systematic review of 'grommets (ventilation tubes) for hearing loss associated with otitis media with effusion in children'[166] concluded that the benefits of

grommets appear small and the effects on hearing diminish during the first year after surgery.

From the trials reviewed, grommets were beneficial in the first 6 months. At 3 months, the mean hearing was 12 dB better in those receiving grommets, falling to 4 dB at 6–9 months. Using pure tone audiometry as a surrogate for disability due to hearing loss fails to address the potentially complex disadvantage the developing child suffers during the period of untreated hearing loss. While the review reports no proven effects on language, speech development, behaviour, cognitive or quality of life, there is some trial evidence to support effects in these domains from published data.[113–123]

Uncertainties remain as the evidence collected in the review cannot entirely resolve discrepancies between analysed trial data on the one hand and parental and clinical observation of a beneficial treatment effect observed in practice on the other. This may be in some part due to a lack of validated and reliable child and parent-centred measures, lacking in many of the trials (with perhaps hitherto some overreliance on hearing level), while also duly acknowledging discrepancies arising from lack of control for placebo effects and other biases inherent in clinical practice.

The remaining challenge is to identify those children for whom intervention is needed and helpful.[167] Does a return to normal pure-tone audiometry after 12 months of hearing loss from OME equate to absence of disability during the same period? In considering data from randomized controlled trials, the effect of intervention may appear reduced in an intention to treat analysis (ITT), when the rate of transfer from control to intervention group is high (contaminates the control group with the intervention effect). However ITT does control for attrition bias and is the most appropriate and robust analysis when evaluating effectiveness and cost-effectiveness in the NHS setting.

The UK MRC TARGET multicentre study looked at the effect of ventilation tubes alone or with adjuvant adenoidectomy on child-centred outcomes. Children aged between 3.5 and 7 years, with bilateral OME, persistent over a 12-week 'watchful waiting' period and associated with a hearing impairment in both ears of 20 dB HL or poorer were eligible for inclusion. They were randomized to one of three arms: no-surgical management, bilateral ventilation tubes (Shepard) or bilateral ventilation tubes with adjuvant adenoidectomy. In the non-surgical group, hearing improved with time, mainly due to the natural resolution of the OME. Children randomized to have ventilation tubes had a marked improvement of 12 dB 3 months following surgery compared with the non-surgical group. In both ventilation tube groups, the hearing at 3 months does not become 'normal' (i.e. 0 dB HL). If one excludes the small number of ears in which the ventilation tube is non-functioning, there is still an air–bone gap of 13 dB.[168] At all other post-operative visits, when a tube was functioning, the air–bone gap was of a similar magnitude and, as the middle ear space was well-ventilated, was considered due to effusion and oedema around the ossicular chain.

The difference in hearing between the two surgical groups and the non-surgical group became almost negligible at 12 months. The reason for the deterioration in the hearing levels over time in those with a ventilation tube was due to a combination of two factors. First, the proportion of tubes that become non-functioning increased with time, though children were eligible to have them reinserted if the hearing entry criteria were satisfied at that time. The other reason was that, in ears where the ventilation tube has extruded and the OME has resolved, there is still a small but material conduction deficit of approximately 14 dB.[168] The reason why those in the non-surgical arm improved over that period was mostly due to the natural spontaneous resolution rate of the OME combined with a much smaller contribution from those who switched management arms to surgery.

TARGET demonstrated the improvement in hearing from ventilation tubes averaged over the first year was 5.7 dB. In the second year, the difference between the two groups became negligible. Hence, when averaged over 2 years, the benefit of ventilation tubes is reduced to 3.1 dB. A more recent individual data meta-analysis of four trials that randomized children to ventilation tubes or watchful waiting confirmed the benefit of short-term ventilation tube at 6 months but not at 12 months, with a magnitude of difference of 4.5 dB.[169]

In this same study, the meta-analysis from seven trials randomized 1232 children with persistent bilateral OME for 12 weeks to ventilation tubes or non-surgical management. The only factor predictive of a better hearing outcome at 6 months was attendance at day care with an impairment of 20–25 dB in both ears. Those not attending day care had no benefit (>1 dB) at 6 months. No effect of age, sex or socioeconomic group was evident. In three trials which randomized children 'by-ear', those with a binaural hearing level of >25 dB HL benefited by 10 dB at 6 months compared with the 4 dB of those with lesser hearing thresholds. These data suggest that, when the aim is improvement in the hearing, then younger children at day care and those with binaural hearing thresholds poorer than 25 dB HL and persistent over at least 12 weeks will benefit most.

Non-hearing outcomes are discussed in 'Outcomes of childhood OME' above.

Outcomes of adenoidectomy

The role of the adenoid in OME has been discussed above. Chronic inflammatory change in the mucosa of the Eustachian tube and middle ear secondary to biofilm infection of the adenoid rather than physical obstruction of the Eustachian tube is the likely cause, and removing this is how adenoidectomy is beneficial in the management of OME. Adenoidectomy reduces the need for reinsertion of ventilation tubes.[170, 171] At the time of writing, UK guidance[104] does not yet include the recommendation for adjuvant adenoidectomy. While clinicians recommended this for the 2011 NICE guideline update, the guideline was not changed. The US guideline does not recommend adjuvant adenoidectomy until the second insertion of ventilation tubes;[171] this might be appropriate guidance for the younger age group, given the role of the adenoid in laying down immune memory, discussed above.

Hearing In the TARGET trial, adenoidectomy at the time of insertion of ventilation tubes doubled the benefit and extended better hearing through the second year following intervention, reducing the need for repeat insertion of ventilation tubes, with an absolute risk reduction of 21%.[130]

Upper respiratory tract symptoms Adjuvant adenoidectomy confers the additional benefit of improved respiratory health over a 2-year period following surgery (Haggard MP, 2005, personal communication).

COMPLICATIONS OF VENTILATION TUBES

Operative

The most common operative complication is displacement of the ventilation tube into the middle ear, in 0.5% of cases. The tube should be retrieved if damage can be avoided. If not, the inert nature of the tube means that significant further problems are unlikely to occur. Efforts should be made to retrieve the tube at the time, but failure to remove it seldom causes problems. Posterosuperior myringotomy must be avoided as this risks damage to the ossicular chain and incudostapedial joint. Very rarely, a high dehiscent jugular bulb may be pierced by an inferiorly placed myringotomy.

Early post-operative

Aspiration at the time of surgery is unlikely to prevent blockage of the lumen of the ventilation tube.[156, 157] Early infection around the ventilation tube occurs in 9% of ears.[172] Topical antibiotic steroid drops at the time of surgery can reduce the incidence to 1%. Although likely to be safe in clinical practice,[173] aminoglycoside drops carry the potential risk of both ototoxicity and vestibulotoxicity and should be avoided. Quinolone antibiotic eardrops are a safer alternative and, although widely used worldwide, are currently unavailable in the UK. Quinolone eye drops (e.g. ofloxacin) are commonly used for this non-licensed indication.

Otorrhoea Otorrhoea in association with a ventilation tube *in situ* may follow an acute upper respiratory tract infection or can be the result of a chronic biofilm infection of the ventilation tube itself. Post-operative otorrhoea is the most common complication with a reported incidence of 10–50% (**Figure 13.7**). A Cochrane review failed to find good quality evidence to support a meta-analysis. While oral amoxicillin clavulanate combined with daily aural toilet was significantly more effective than placebo and daily aural toilet, no significant benefit could be shown for topical aminoglycoside preparations compared with each other or with oral steroids and oral antibiotics.[174] In a randomized, double-blind, controlled trial, topical ciprofloxacin drops were superior to topical saline and systemic antibiotics in managing ventilation tube otorrhoea. Failure rates were 23%, 58% and 70% in the groups treated with topical ciprofloxacin, topical saline and oral amoxicillin respectively.[175] A randomized, blinded parallel group study compared ciprofloxacin–dexamethasone ear drops with no treatment following ventilation tube insertion. In the treatment group, otorrhoea was observed in 4.95% of patients, compared to 39.39% of the untreated group ($p < 0.0001$).[176]

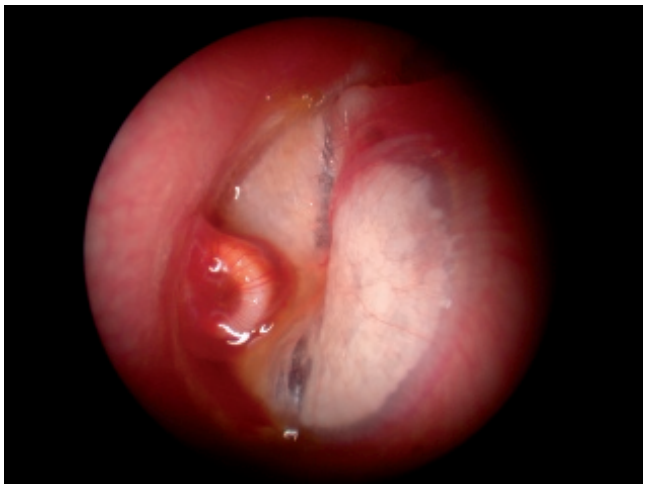

Figure 13.7 Right tympanic membrane with infected grommet. (Image courtesy of Mr Michael Saunders.)

Granulation tissue secondary to infection occurs in approximately 1%, and is similarly managed with topical preparations. Chronic infection of the ventilation tube may require removal of the tube (in approximately 4% of ears).[172] Ofloxacin as a topical antibiotic is preferable to ciprofloxacin, minimizing the risk of antibiotic resistance in a systemically used antibiotic.

Late post-operative

Hearing loss A study of 224 children following grommet insertion concluded that 25 years after surgical treatment for OME hearing was no different to age- and gender-matched controls. Neither myringotomy alone nor insertion of ventilation tubes resulted in a significant difference in long-term hearing level, compared to a gender-matched normative data set. Where myringosclerosis was present in ears following grommet insertion, there was a small associated loss (4–5 dB) in the high-frequency range. Where pars tensa atrophy occurred after grommet surgery, the long-term change in hearing was limited to an overall loss of 3–4 dB.[177]

Myringosclerosis ('tympanosclerosis') The most common structural complication after ventilation tube surgery is myringosclerosis, occurring more often with long-term tubes. Hyaline degeneration of the collagen tissue in the fibrous layer of the pars tensa is visible otoscopically as localized white patches or plaques (**Figure 13.8**). These do not occur in the absence of a history of otitis media. The frequency of myringosclerosis increases with the frequency of OME with an increased risk if a ventilation tube has been inserted.[166] While there was difference between short- and long-term tubes in this review, a later systematic review concluded that myringosclerosis was more common with long-term tubes.[178] This review

Figure 13.8 Myringosclerosis 'tympanosclerosis'. (Image courtesy of Mr Michael Saunders.)

Figure 13.9 Perforation. (Image courtesy of Mr Michael Saunders.)

also concluded no hearing impairment resulted from the presence of myringosclerosis.

Tympanic membrane perforation When a ventilation tube extrudes, the initial pars tensa perforation usually heals. A perforation may then subsequently reoccur at the same site due to a subsequent episode of AOM and, again, will normally heal spontaneously. Perforation is seen in between 1% and 6% of ears that have had a ventilation tube and in 1% of ears that have never had a ventilation tube inserted; perforation occurs more commonly in treated ears, and more often with long-term ventilation tubes (**Figure 13.9**).[179]

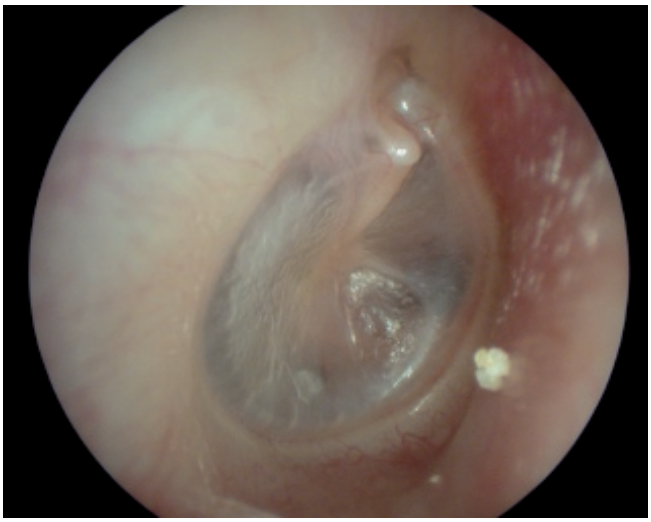

Figure 13.10 Pars tensa atrophy. (Image courtesy of Mr Michael Saunders.)

Pars tensa atrophy and retraction Thinning and retraction of the tympanic membrane are complications of persistent OME. In children initially referred with bilateral OME, pars tensa retraction to the incus or promontory (Sade grade 3/4) occurs in 8% of the better- and 10% of the poorer-hearing ears.[63] These retractions were not associated with a history of longer ear problems. Followed up over a 12-week watchful waiting period, they resolved in 69% of the better and 65% of the poorer ears. The OME had also resolved in 14% of the better and 10% of the poorer ears with a pars tensa retraction, respectively.

Pars tensa atrophy (**Figure 13.10**) also occurs in approximately 3% and retraction to the incus or promontory in 2% of ears in 7–8-year-old children in whom there is no history of OME. This incidence is similar to that in children with transient episodes of OME. However, the incidence of atrophy, but not of retraction, increases to approximately 9% in those with persistent OME. In those who still have a ventilation tube *in situ* for their OME, the incidence of atrophy increases to approximately 68% and retraction to approximately 14%. It could be argued that this increase in ears with a ventilation tube still *in situ* is because these are more persistent cases, rather than because of the ventilation tube itself. This is in part supported by the fact that the incidence is the same with short- and long-term tubes.[173] It can be concluded that ventilation tubes do not prevent the occurrence of atrophy or retraction and should not be inserted for that reason alone. Cholesteatoma is uncommon enough to make it difficult to draw clear conclusions about the effect of ventilation tube insertion on the incidence of this condition.[178]

Swimming and water contamination A meta-analysis concluded that for bathing and swimming, but not diving, ear protection does not or only slightly reduces otorrhoea in children following ventilation tube insertion.[178]

Hearing aids

Hearing aids can be used in children with persistent OME, to avoid repeated surgery, or where parents wish as their preferred initial management. Repeated visits for new ear moulds, maintenance of the aids and replacement of lost aids suggest this option might be time- and cost-intensive for both parents and providers. There is very limited published data on the subject. In a small case series,[179] hearing aids were acceptable to the majority of parents and gave aided thresholds with a mean of 17 dB, in the same range as expected of ventilation tubes. The main concern is potential noise trauma, as up to 13% of children become dependent on the aids and wish to continue to use the aids after the OME has resolved.

The Softband® bone-conduction aid incorporates a bone-anchored hearing aid in a headband. In a small prospective, non-randomized questionnaire study of 11 children aged between 6 and 15 years, half the children found daily listening situations to be mostly easy. All of the children used the Softband® at school. This is an older age group than those typically presenting with OME, but this small study indicates the need for a larger trial to assess the potential benefit of this non-invasive treatment of OME.[180]

Management of OME in children with related comorbidity

Even after surgical repair, children with a cleft palate have a high incidence of OME that in some is a persisting condition. Hearing aids rather than ventilation tubes are usually recommended to maintain near-normal hearing without the complications associated with repeated ventilation tube insertion or long-term tubes.[181] Similar constraints apply to the management of OME in children with Down syndrome, where there might also be a sensorineural component to the hearing loss.[182]

BEST CLINICAL PRACTICE

In primary care

OME should be suspected in children with 'ear-related concerns' who may have recently recovered from an episode of acute otitis media or are suffering from recurrent bouts.

- ✓ All children should have routine otoscopy to help confirm OME and distinguish it from AOM or COM. However, even with good training, otoscopy is unlikely to be sufficiently sensitive or specific to reliably make the diagnosis of OME on its own. Tympanometry with training of staff is likely to be more accurate in diagnosing if effusions are present.
- ✓ Free-field voice testing is a valid assessment of hearing in a primary care setting. Hearing-related QOL can also be estimated using the OMQ-14 (short form) questionnaire.
- ✓ No medical therapy (including antibiotics, topical nasal steroids, systemic steroids, nasal decongestants and mucolytics) has been proven to be clinically effective. Alternative and complementary therapies have not been shown to be effective in the management of OME either. In older children, autoinflation might be beneficial.
- ✓ It is important that all parents of children with OME receive appropriate general counselling about the natural history and nature of the condition. This includes advice regarding hearing tactics.
- ✓ If there is concern regarding the hearing in any child, referral for hearing assessment is indicated. For children under the age of 4 years, initial referral is to community paediatric audiology. In children aged 4 years and older, hearing assessment can be performed in a general paediatric ENT clinic. Active monitoring (watchful waiting) with audiometry can be continued in secondary care.

In secondary care

- ✓ Otoscopy, tympanometry and pure-tone air-conduction thresholds should be assessed in all children referred with suspected hearing impairment at their first clinic visit. Non-masked bone-conduction thresholds are generally obtainable in children over the age of 4 years. This will aid management of those with OME and detect previously undiagnosed sensorineural hearing loss.
- ✓ Primary carers of all children with OME should receive appropriate general counselling about the natural history and nature of OME.
- ✓ The hearing levels associated with the child's OME should be discussed with the parents and advice about hearing tactics given to help the parents mitigate any disability.
- ✓ Children with OME whose hearing thresholds do not satisfy the hearing criterion of 25 dB HL bilaterally should be followed up 12 weeks later with repeat audiometry.
- ✓ Where hearing loss of 25 dB HL or poorer in both ears persists after 12 weeks of active monitoring, discuss options for further management, including insertion of ventilation tubes with adenoidectomy, hearing aids or continued surveillance.
- ✓ While the risk of ototoxicity with topical aminoglycoside preparations is small, for the treatment of infected otorrhoea and where bacterial sensitivities allow, use quinolone ear drops when a grommet is patent or there is a tympanic membrane perforation.

FUTURE RESEARCH

- ➤ Different impact of OME and elevated hearing thresholds in children with different intellectual ability.
- ➤ Possible benefits of surfactant in the management of adenoidal biofilms.

KEY POINTS

- In children, the prevalence of OME is bimodal with the first and largest peak at 2 years of age (~20%) and the second peak at around 5 years of age (~16%).
- For each episode, resolution without treatment of the OME is the most likely outcome.
- The effect of hearing impairment on speech, language, cognition and behaviour may produce measurable changes long after the OME has resolved.
- Attic retractions are an OME disease effect with an incidence of approximately 14% in the most severely affected children. The proportion of these retractions that progress to cholesteatoma is unknown. There is no evidence that the risk of developing an attic retraction and the potential to develop a cholesteatoma is altered by the insertion of ventilation tubes.
- The benefit of ventilation tubes in children under 3 years of age with significant language, development or behaviour problems requires investigation. In children over the age of 3 years, the binaural hearing average is used as a surrogate of behaviour and for impact upon quality of life.
- All children with hearing thresholds of 25 dB or poorer in both ears should have their hearing documented over a 12-week watchful waiting period before any decisions regarding surgery are made.
- If ventilation tubes are to be inserted, adenoidectomy is effective adjuvant treatment, extending the period of benefit to the hearing of short-term ventilation tubes up to 2 years and reducing the proportion of children eligible for reinsertion of short-term tubes from around 50% to 25%. This effect is likely to be greatest in the oldest children. (Adenoidectomy in children under the age of 3 years might impact negatively on immune system development.)

ACKNOWLEDGEMENTS

The authors gratefully acknowledge the following people. Professor George Browning, MRC Institute of Hearing Research, Glasgow, author of the OME chapter in the 7th edition of *Scott Brown's Otolaryngology*. Parts of that chapter have been retained in this rewriting and update. Professor Mark Haggard CBE, External Scientific Staff, Cambridge University, for advice and input on the 'Quality of life' section of this chapter. Mr Michael Saunders, Consultant Paediatric Otolaryngologist, Bristol, for the digital images of tympanic membranes used in the chapter.

CHAPTER 14

ACUTE OTITIS MEDIA

Peter A. Rea and Natalie Ronan

SEARCH STRATEGY

Data in this chapter may be updated by searches of Medline and the Cochrane Controlled Trials Register, using the keywords acute otitis media. Reference lists were reviewed for further articles, and authors of recent presentations contacted personally for their reference lists.

INTRODUCTION

For such a common childhood infection, acute otitis media (AOM) remains something of an enigma. It is hard to diagnose accurately and on existing evidence, as opposed to custom and tradition, there is still a high level of uncertainty over how it should best be treated. This is against a background of increasing bacterial resistance to antibiotics. There is plenty of evidence in the literature of the relative frequencies of viral and bacterial pathogens in AOM, but this is often of little help to the clinician on the spot in an individual case. Some of the epidemiological evidence is also relatively 'soft', since it is based on the flawed premise that AOM can accurately be diagnosed from the history and otoscopy alone, unsupported by tympanometry or tympanocentesis. In this chapter the authors have tried to thread their way through the often conflicting evidence about the practical management of AOM at the same time as covering what is known of the pathology, epidemiology and complications of this commonest of childhood illnesses.

Many areas of uncertainty, insufficient evidence and limited information about AOM remain. For this reason we have indicated Level 1 and Grade A evidence in the chapter. Even a meta-analysis, the supposed gold standard of evidence, is only as good as the studies it covers. It must be remembered that the prevalence of otitis media with effusion (OME), 'glue ear', only began to be widely appreciated after the development of the twin tools of universal hearing screening and the tympanometer, in the 1960s and early 1970s respectively. The accuracy of correct reporting of cases of AOM lags behind that of OME mainly because the essential presence of fluid in the middle ear is not confirmed by tympanometry and audiometry in the majority of large population studies of AOM.

DEFINITION

Acute otitis media (AOM) may be defined clinicopathologically as inflammation of the middle ear cleft of rapid onset and infective origin, associated with a middle ear effusion and a varied collection of clinical symptoms and signs. It is synonymous with acute suppurative otitis media. It normally develops behind an intact tympanic membrane but may include acute infections arising in the presence of ventilation tubes or existing tympanic membrane perforations. The requirement to confirm a middle ear effusion, and the nature of the symptoms and signs, vary between authors.[1, 2]

The literature supports four broadly defined subgroups of AOM:

1. **Sporadic** episodes occurring as infrequent isolated events, typically occurring with upper respiratory tract infections (URTIs)

2. **Resistant** AOM: persistence of symptoms and signs of middle ear infection beyond 3–5 days of antibiotic treatment
3. **Persistent** AOM: persistence or recurrence of symptoms and signs of AOM within 6 days of finishing a course of antibiotics
4. **Recurrent** AOM: either 3 or more episodes of AOM occurring within a 6-month period, or at least 4–6 episodes within a 12-month period (no consensus has been reached on the latter).

Groups 2 and 3 appear similar at first glance and this distinction may be questioned. It is included to maintain some consistency with the wider literature.

Grading of the severity of an episode has been attempted and has merit both clinically and for research. Pyrexia from 37.5 °C to 39 °C, vomiting and severity of otalgia have been used.[3, 4]

DIAGNOSIS

Diagnosis is based on the combination of often non-specific symptoms, evidence of inflammation of the middle ear cleft, and by some authors by the additional confirmation of a middle ear effusion. Diagnostic difficulty has affected the quality of research into AOM. There may well not be a clear history of a crescendo of otalgia in a coryzal child, followed by rapid symptomatic relief associated with tympanic membrane perforation and associated blood-stained otorrhoea. The difficulty in establishing clear diagnostic guidelines has been highlighted in an analysis of 80 studies of AOM.[5] In diagnosing AOM only 52.5% of the studies cited middle ear effusions, 32.5% included symptoms and signs of inflammation and 2.5% considered the rapidity of onset. Clinicians recognize this difficulty. A large multinational study rated clinicians' diagnostic certainty in children under 1 year of age at only 58%, rising to 73% in those over 31 months.[6]

Symptoms

Diagnosis by symptomatology alone is inaccurate because of the young age of most patients, and the non-specific nature of the symptoms. One third of children may have no ear-related symptoms. Two-thirds may be apyrexial.[7] Symptoms suggestive of AOM include rapid onset of otalgia, hearing loss, otorrhoea, fever, excessive crying, irritability, coryzal symptoms, vomiting, poor feeding, ear pulling and clumsiness (Table 14.1). AOM most commonly develops 3–4 days after the onset of coryzal symptoms. The otalgia will settle within 24 hours in two-thirds of children without treatment.[9] The otorrhoea, if present, is mucopurulent and may be blood-stained. Symptomatic relief is obtained without treatment in 88% by day 4–7. The hearing loss, caused by the middle ear effusion, occurs early in the illness and may persist at greater than 20 dB for 1 month in over 30%, and 2 months in 20% of children.

Signs

The child may appear unwell, and may rub his or her ear. The diagnosis is often confirmed, rightly or wrongly, by an attempt at otoscopic assessment of the tympanic membrane. However, a poorly functioning otoscope, the moving target of a child's head, the narrow ear canal of an infant, the natural redness of the tympanic membrane of a screaming child, wax, and above all the inaccuracy of an untrained (or even trained) eye straining to interpret a two-dimensional image, all combine to make otoscopy an imprecise art. Since trained observers have been shown to have only an 85% accuracy in otoscopic diagnosis,[10] it would not be surprising for a sensible primary care physician to rely more on history and the general aspect of a child than on otoscopic findings. With these reservations, diagnosis may be supported by otoscopic assessment of tympanic membrane **colour**, **position** and **mobility**. In AOM the tympanic membrane is usually opaque. It is most commonly yellow, or yellowish pink in colour, being red in only 18–19%.[7, 10] The position of the tympanic membrane reliably predicts AOM only when it is bulging. Hypomobility of the drum demonstrated by pneumatic otoscopy has been shown to aid diagnosis[10] and is felt essential in some countries,[1] though others including the Dutch[2] take a more pragmatic view and do not include this in their diagnostic criteria. Should the drum be perforated, or a ventilation tube be *in situ*, mucopurulent otorrhoea will be seen.

Investigations

Tympanometry may be used to establish the presence of a middle ear effusion but is not usually available. Tympanocentesis and culture of middle ear effusion have been used in a number of studies assessing diagnostic

TABLE 14.1 Relation of reported symptoms to presence of AOM in 302 children under 4 years of age (reprinted from Heikkinen and Ruuskanen,[8] with permission)

Symptom	Sensitivity	Specificity	Positive predictive value	Negative predictive value
Earache	60	92	83	78
Restlessness	64	51	46	68
Rhinitis	96	8	41	74
Cough	83	17	40	61
Fever	69	23	38	53

accuracy of clinical signs, and establishing the organisms prevalent in a community. It is rarely required to make the diagnosis, though may be considered in high-risk children such as the immunocompromised, an unwell neonate, those that fail to respond to conventional treatment, and children who are seriously ill or have complications of AOM. Taking a bacterial swab of persistent otorrhoea following perforation is recommended. Nasopharyngeal swabbing for bacterial culture has been assessed but the correlation with middle ear organisms has been too weak to recommend it clinically.[11]

Specific investigation may be prompted by recurrent AOM not responsive to conventional treatment. Both iron-deficiency anaemia and white blood cell disorders have been associated with AOM, so a full blood count is indicated. Immunoglobulin assay may be appropriate: IgA, IgG (with subclasses) and IgM are typically assessed. Children with recurrent infection of ventilation tubes may also merit investigation for primary ciliary dyskinesia, particularly if nasal and pulmonary symptoms coexist.

Differential diagnosis

Pain may be referred from tonsillitis, teething, temporomandibular joint disorders, or simply be the result of an uncomplicated URTI. In a screaming child the tympanic membrane may well appear red. Diagnostic confusion may occur with acute mastoiditis, OME, otitis externa, trauma, Ramsay Hunt syndrome and bullous myringitis. Very rarely AOM may be the first indication of serious underlying disease such as Wegener's granulomatosis or leukaemia.

AETIOLOGY

Microbiological, anatomical and environmental factors combine with altered host defence mechanisms to predispose to infection. Genetic predisposition to recurrent AOM is being cited increasingly in the literature.

Infective agents

AOM results from infection of the middle ear cleft. Both viral and bacterial infections are implicated. These infections may occur in isolation or combination.

VIRUSES

Clinically, it is apparent that AOM is commonly associated with viral upper respiratory tract infections. As our ability to identify these improves, the role of viruses in the aetiology of AOM is becoming clearer. Increasing use of polymerase chain reaction assays for respiratory viruses suggests 60–90% of cases of AOM may be associated with viral infection.[12] In one study a specific viral cause of URTI was shown in 41% of children with AOM.[13] The viruses most commonly associated with AOM vary between studies, but in decreasing frequency include: respiratory syncytial virus (RSV), influenza A virus, parainfluenza viruses, human rhinovirus and adenoviruses. This heterogeneity is important when considering vaccination against viruses as a prophylactic measure.

The mechanism by which they give rise to AOM is likely to vary between viruses.

Viral material has been demonstrated in the middle ear aspirates of children with AOM in 48–71% of cases.[12] The viral material may either arrive passively along the Eustachian tube along with other nasopharyngeal secretions, or actively invade the middle ear cleft possibly by haematogenous spread. These alternative routes of entry are suggested by the wide variation in rates of isolation of specific viral strains in the middle ear during systemic infection, ranging from 4% to 74% of cases dependent upon the specific virus. If all arrived passively, similar rates of isolation would be expected. This implies that some viruses may be actively invading the middle ear cleft, and may be contributing directly to mucosal inflammation. Respiratory syncytial virus invaded the middle ear most frequently.[13] In contrast, those arriving passively appear to cause AOM by virtue of their action on the Eustachian tube, on bacterial adherence and on host immunity.

There is good clinical and animal evidence that viral infection affects Eustachian tube function.[12] At a cellular level there is release of multiple inflammatory mediators from cells within the nasopharynx. Ciliated epithelial cells numbers decline, mucus production increases in the Eustachian tube, and negative middle ear pressure results. This is likely to predispose to AOM.

Alteration of host immunity has been documented after viral infections, increasing susceptibility to bacterial infections. Cell-mediated immunity has been shown to be affected by RSV infection and neutrophil function altered by influenza viruses. In a study of children with bronchiolitis caused by RSV, 62% developed AOM. Bacteria were isolated from the middle ear in all these children.

The ability of bacteria to colonize and adhere to the nasopharyngeal epithelium appears to be increased by certain viral infections. Increased colonization by pathogenic bacteria may predispose to AOM.

Viral and bacterial infections coexist in the middle ear cleft in AOM in as many as two-thirds of cases where viruses have been identified. This is important as clinical studies show that children who have both viruses and bacteria in their middle ear are very much more likely to have a poor response to antibiotics when compared to those with bacteria only (33% versus 3% failure respectively, in one study[14]). Why this should be is unclear, but it may be related to the greater concentrations of inflammatory mediators in ears in which both bacteria and viruses are present.

BACTERIA

Streptococcus pneumoniae (pneumococcus) is the most common bacteria isolated from the middle ear in AOM, and it has been reported in 18–55% of cases. There are, however, some 90 serotypes. *Haemophilus influenzae* has been isolated in 16–37%, and *Moraxella catarrhalis* in 11–23% of cases.[15] Less frequently reported

are *Streptococcus pyogenes* in up to 13% of cases and *Staphylococcus aureus* in up to 5%.[16]

In persistent or recurrent bacterial AOM, repeat culture of middle ear aspirates has failed to grow pathogenic bacteria in 30–50% of patients, implying that inflammation may persist despite the eradication of the infecting organism. The role of biofilms is the subject of intensive study at present. The spectrum of organisms is similar to that in isolated episodes. In the 1980s *H. influenzae* was the most common organism identified in persistent or recurrent AOM, but this has been replaced by drug-resistant pneumococcus. After antibiotic treatment for recurrent AOM it is now estimated that 50% of *H. influenzae* are beta-lactamase producing. A similar proportion of pneumococci are penicillin-resistant.[16] Penicillin resistance in pneumococci results from decreased penicillin-binding protein on the bacterial cell walls so reducing the affinity for penicillin-related drugs, but this means that resistance may often be overcome by increasing drug dosage. This is not the case with beta-lactamase producing organisms. Most *M. catarrhalis* are now beta-lactamase producing.

Studies on HIV-positive children suggest a similar spectrum and prevalence of infecting organisms as occurs in immunocompetent children, except where the child is severely immunosuppressed where a higher percentage of *Staphylococcus aureus* has been reported.

Routes of spread of infection

Three potential routes are described: the Eustachian tube, tympanic membrane perforations or grommets, and haematogenous.

The Eustachian tube is traditionally assumed to be the main route by which organisms reach the middle ear, though there are relatively few studies to confirm this. It is speculated that negative middle ear pressure may facilitate the movement of bacteria up the Eustachian tube.[17] Circumstantial evidence is also gained from similarities in organisms cultured from the postnasal space and the middle ear cleft in AOM. Whether anatomical or physiological differences predispose to AOM is unclear. Studies of American Indians, who are prone to otitis media, suggest their Eustachian tubes are shorter, straighter and more patulous than in whites, but also that they have a low passive tubal resistance.[18] Research has found no difference in tubal dimensions in otitis prone and non-prone children. However, altered tubal function may play a role. Specifically, otitis-prone children have been shown to have significantly poorer active tubal function (muscular opening function).

Pathogen entry through tympanic membrane perforations or ventilation tubes is most commonly associated with water exposure.

Haematogenous spread is inferred from the evidence provided by studies of viral identification in the blood and middle ear described previously. It was shown that the wide variation in rates of identification of specific viral strains from the middle ear could not be explained by passive Eustachian tube transport alone.[12]

Risk factors

GENETIC FACTORS

There is growing evidence that recurrent AOM is largely genetically determined. It is likely that many genes are involved. There are numerous studies suggesting a familial association. A meta-analysis of risk factors has shown that, when one family member had had AOM, the risk increased for other family members (relative risk 2.63).[19] Racial differences are well described, with increases in American Indians, Inuits and Australian Aboriginals. However, environmental factors, such as poor economic status, may contribute to the increased risks in these groups. The most powerful evidence comes from twin studies, in particular comparison of monozygotic and dizygotic twins in whom the occurrence of AOM was compared.[18] Many immune-related mechanisms, which are likely to have a genetic basis, have been proposed. Certain HLA classes have been shown to be significantly associated with increased risk of AOM. Maternal blood group A is reported to an independent risk factor (relative risk 2.82). Atopy has also been associated with increased risk of developing AOM. **[Level 1, 2 and 3 evidence]**

IMMUNE FACTORS

Our understanding of the immune response to AOM remains incomplete. However, a number of specific associations have been identified which suggest that certain defective or immature pathways may predispose to infection. Low levels of IgG2 subclasses have been reported in several studies to be more common in otitis-prone children. Those with IgG2 deficiency were shown to be three times more likely to develop post-ventilation tube insertion otorrhoea, for example. Delayed maturation of anti-pneumococcal antibodies (IgG1 and IgG2 were studied) does appear to predispose to AOM. This may explain in part why children grow out of AOM as immunity matures.

Defective complement-dependent opsonization has been associated with recurrent AOM and diarrhoea in infancy.[18] This is caused in some examples by low concentrations of mannose-binding protein which acts as an opsonin. This appears to be a common defect with over 20% of children with recurrent AOM affected in some studies. This may be particularly important in infancy when the antibody repertoire is limited.

Aberrant expression of critical cytokines such as tumour necrosis factor and interleukins, resulting in suboptimal host defence, has been postulated as a cause for persistent infection. Expression of mucin genes, at least nine of which have been identified, may differ in those predisposed to AOM. Middle ear mucosa expresses specifically the *MUC5B* gene. Mucin genes regulate the production of mucin. Limited evidence is beginning to emerge that overexpression may alter the mucociliary transport system.[18]

A number of studies of children with HIV infection have yielded conflicting results. Advanced disease associated with low CD4 counts does seem to be associated with an increased incidence of AOM.

ENVIRONMENTAL FACTORS

There are many reports on the relative contribution of environmental factors. These are important as it may be possible to modify them. The most important is almost invariably stated to be day-care attendance outside the home. The larger the number of children in the group, the greater the risk. Day care outside the home carries a relative risk (RR) for AOM of 2.45, compared to a risk of 1.59 for children cared for in their own home. The incidence of AOM appears to follow that of seasonal URTIs in the winter months. Breastfeeding for 3 months is protective (RR 0.87). Use of a pacifier (dummy) carries a relative risk of 1.45.[19] Poor socioeconomic status associated with poor housing and overcrowding has been reported to be associated with AOM (e.g. overcrowding: RR 5.55 in a Greenlandic population). Passive smoke exposure from parental smoking is weakly associated (RR 1.0–1.6). There is more limited evidence to support the role of dietary factors, in particular cow's milk allergy, in predisposing to AOM. [Level 1 evidence]

Syndromic associations

Syndromes associated with abnormalities of skull base anatomy are well recognized as being associated with chronic middle ear disease, but less is published on associations with AOM. Children with Turner syndrome do suffer more frequent episodes of AOM. Down syndrome predisposes to middle ear disease including AOM. In cleft palate there is only a minor increase reported. Certainly Eustachian tube dysfunction in these groups predisposes to middle ear effusion, but it is not clear whether it is this dysfunction or an increase in risk secondary to subtle immunological factors that predisposed to infection. No increase is found in children with primary ciliary dyskinesia if grommets are not inserted, or cystic fibrosis.

A direct association between iron-deficiency anaemia, and the degree of anaemia, and frequency of AOM has been reported.

EPIDEMIOLOGY

AOM is one of the commonest illnesses of childhood. It accounts for about 25% of all prescriptions for children under 10 years of age in the USA, for example. Its incidence appears highest in the first year of life, more specifically the second 6 months of life in most studies, and gradually reduces with increasing age. This progression was shown by Strangerup[20] who reported an incidence of a first episode of AOM in 22% in the first year of life, 15% in year 2, and 10% in year 3, falling to 2% by year 8 (**Figure 14.1**). Epidemiological studies have been compromised by difficulty in achieving accuracy in diagnosis when large numbers of children are being assessed, hence there are wide variations in reported numbers. Incidences of over 60% are stated in some reports of infants up to age 1 year. By age 3 years some 50–70% of all children will have had at least one episode of AOM, and at least 75% by age 9 years.

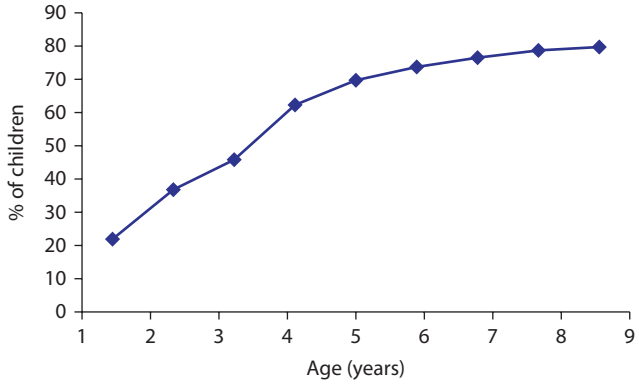

Figure 14.1 Cumulative incidence of acute otitis media (i.e. how many children have had at least one episode in their life). (From Strangerup and Tos,[20] with permission.)

The incidence of AOM certainly varies with the seasonal incidence of viral upper respiratory infections. There are reports that it is increasing over a period of years. Possible reasons include increased day nursery attendance, and changes in diagnostic awareness.

Recurrent AOM has been reported in 5% of children under 2 years of age. Others have reported that by age 3 half of children will have had at least three episodes. An important indicator of future problems is a first episode before 9 months of age: these children have a 1 in 4 risk of developing recurrent AOM.

In the first 2 years of life AOM occurs bilaterally in 80% of cases. After 6 years of age it is unilateral in 86%.[20]

MANAGEMENT OPTIONS

Most children with AOM will get better quickly and without treatment. Some will not. A very small number may develop potentially serious complications. Current debate questions whether and for whom treatment is required, and the role of prophylactic strategies. As serious complications are rare, it can be difficult to obtain high-quality evidence of how effective are prophylaxis and the treatment of episodes of AOM in preventing such complications.

Management of acute episodes

CONSERVATIVE TREATMENT

Most children will benefit from simple analgesics and antipyrexials, in a quiet supportive environment. Paracetamol and ibuprofen are most commonly used in the UK. There is limited experimental animal evidence showing that ibuprofen provides additional benefit by reducing mucosal inflammation when taken in combination with amoxicillin.

MEDICAL TREATMENT

Antibiotics

Uncertainty over the use of antibiotics is reflected in wide variations in usage between countries, ranging from 31%

in the Netherlands to 98% in the USA.[9] There is, however, an increasingly good evidence base for the most appropriate management in children over 2 years of age. In children under 2 the evidence base is weaker.

A recent meta-analysis has addressed the efficacy and safety of antibiotic treatment in children with AOM. Two-thirds of children were shown to recover within 24 hours regardless of treatment. However, antibiotics did have a small beneficial effect on subsequent pain levels, with one third experiencing less pain after 2–3 days and one quarter having reduced pain at 4–7 days. Antibiotics also reduced the number of patients exhibiting abnormal tympanometry at 2 weeks and 2 months, although there was no difference at 3 months. The number of tympanic membrane perforations and contralateral otitis episodes were also reduced in those receiving antibiotics. No effect was demonstrated on late AOM recurrence. However, the occurrence of adverse effects such as vomiting, diarrhoea and rash was significantly increased in the treatment group.[21]

The same review examined the effectiveness and safety of immediate antibiotic treatment against an initial observational approach. No differences were seen between groups in terms of pain, persistence of abnormal tympanometry, tympanic membrane perforations or AOM recurrence, but again the incidence of adverse effects was increased in the immediate treatment group, equating to an adverse event for 1 in every 14 children treated.

Attempts have therefore been made to try to identify a subgroup of children who may benefit from immediate antibiotics. Treatment benefit appears to be most marked in children aged less than 2 years, those with bilateral AOM and those with AOM and otorrhoea. Using short-term symptomatic outcome markers at day 3 has shown that immediate antibiotics may also benefit those children presenting with higher temperatures (>37.5 °C) or vomiting (NNT = 3–6).[4]

The optimum length of a treatment course if commenced has also been addressed in a meta-analysis. Short (less than 7 days) and long (more than 7 days) courses were compared. Risk of treatment failure at 1 month was higher with short courses of antibiotics (absolute difference of 3%) although had no benefit in the longer term. This difference was not observed when using ceftriaxone or azithromycin. In addition, gastrointestinal side effects were reduced when using azithromycin or short-acting antibiotics.[22] In the presence of a tympanic membrane perforation or ventilation tubes, AOM may be treated equally successfully with oral or topical antibiotics. The potential ototoxicity of topical aminoglycoside ear drops in these cases is well recognized and dose-dependent, therefore prolonged topical treatment should be avoided.

Generally, most institutions recommend initial treatment with paracetamol and ibuprofen in uncomplicated cases, with antibiotics to be prescribed if the symptoms worsen or persist for 3–4 days. Immediate antibiotics should, however, be considered if the child is systemically unwell, suffers from significant comorbidities including immunodeficiencies, craniofacial abnormalities or Down syndrome, or if they are under 2 years of age with bilateral AOM, recurrent AOM or tympanic membrane perforation.[2] The usual antibiotic of choice is a 5-day course of amoxicillin, with erythromycin or clarithromycin offered in allergic cases. Guidelines must, however, be adapted to suit local experience, for example in regions of the world with a high incidence of complications of AOM where all patients may be regarded as high risk. **[Level 1 evidence]**

Clinical recommendations for the use of antibiotics in children are summarized in **Box 14.1**.

BOX 14.1 Clinical recommendations for use of antibiotics in children

- Under 6 months of age
- Under 2 years of age with recurrent episodes
- Failure to improve after 2 days of 'watchful waiting'
- More severe symptoms including pyrexia or vomiting, irregular course, or any sign of a complication
- All 'high-risk' children including those with Down syndrome, craniofacial abnormalities, congenital inner ear abnormalities, immunodeficiencies
- Failure to improve after 2–3 days' treatment should lead to change of antibiotic
- Where national guidelines recommend all episodes should be treated

Which antibiotic?

This should be determined by national recommendations. Amoxicillin remains the first choice in most centres, but at higher than previously recommended doses (80 mg/kg/day) if drug-resistant pneumococci are common in a particular country or region, with macrolides for penicillin-sensitive patients. For persistent or resistant episodes, national policies should be sought depending on the prevalence of beta-lactamase producing organisms, and culture results if available. Options include amoxicillin-clavulanate or cefuroxime axetil orally, or intramuscular ceftriaxone (US Centre for Disease Control and Prevention).

Antihistamines and decongestants

A meta-analysis of the use of oral or intranasal antihistamines and/or decongestants concluded that their use could not be supported, and that medication side effects were higher when they were used together. While combining the two treatments was shown to slightly reduce persistent AOM at 2 weeks (NNT = 10.5), the result may have been biased by the design of the studies.[23] **[Level 1 evidence]**

SURGICAL TREATMENT

Surgery has a limited role in the treatment of an uncomplicated episode of AOM. Myringotomy was practised in the pre-antibiotic era, and indeed was continued until the late 1980s in some countries as a first-line treatment for AOM. However, there are now a number of good studies showing that myringotomy plus antibiotics offers no advantage over antibiotics alone. Myringotomy alone has a worse outcome than either of the antibiotic groups.[24]

Myringotomy is reserved for severe cases where complication is present or suspected, to relieve severe pain, or when microbiology is strongly required. [Level 1 evidence]

Management of *recurrent* acute otitis media

ALTERATION OF RISK FACTORS

It may be possible to alter many of the environmental risk factors discussed previously (Box 14.2). Parents should be reassured of the benign natural history of AOM, as these children have been shown to be more demanding than those without recurrent disease, and their mothers more anxious about their care. The most readily modifiable risk factor is exposure to other children. AOM increases with the number of children in day care, the length of time a child spends in day care each week, how young a child is when introduced into day care, the presence of children under 2 years of age in the day-care setting, and having a sibling in day care. Advice should include sitting a child semi-upright if bottle-fed, and avoiding passive smoke inhalation. Restricting the use of pacifiers particularly after infancy should be recommended for otitis-prone children. The mother may be advised to continue breastfeeding for at least 6 months after future pregnancies, and increasing vitamin C intake and avoiding alcohol in the third trimester, both of which have been weakly associated with AOM. The role of food allergies, in particular cow's milk, is still unclear. No effective role has as yet been shown for homeopathic remedies.

BOX 14.2 Modifiable risk factors to discuss with parents

Reduce exposure to other children, e.g. in day-care nursery setting.

Avoid passive smoking.

Sit semi-upright if bottle-feeding.

Avoid the use of pacifiers.

In future pregnancies breastfeed for at least 6 months, and avoid alcohol and increase vitamin C intake in the third trimester.

MEDICAL PROPHYLAXIS

Antibiotics

Antibiotic prophylaxis has the potential to cause problems but can be considered for recurrent AOM. Many organisms need to be covered so a broad spectrum drug is required, although there is no consensus in the literature as to which preparation is superior. Studies of prophylaxis of recurrent AOM invariably treat each individual recurrence with additional antibiotics. Trials therefore compare antibiotic prophylaxis versus placebo between acute episodes. The natural history of recurrent AOM is reassuring. Over 50% of children having no treatment between attacks will not suffer a further episode in the following 6 months. Indeed, only 1 in 8 continues to suffer recurrent AOM (i.e. three or more episodes) during the trials, if treated only for acute episodes. Meta-analysis does, however, show a modest benefit of antibiotic prophylaxis, equating to a reduction of 1.5 episodes per 12 months of antibiotic treatment given, which is about half that expected from the natural history. This suggests that one child would require 8 months of treatment to prevent one episode. However, this effect does not appear to promote longer-lasting benefit after cessation of therapy, and clearly treatment would need to be weighed against the cost of therapy, possible adverse effects and the potential for contribution to bacterial resistance, as well as the potential for masking ongoing active disease.[21]

While the routine administration of prophylactic antibiotics is largely not recommended on the basis of the meta-analysis described above, most trials exclude 'high-risk' children, who are often most in need of treatment. There may therefore be a place for its use in the management of high-risk children with recurrent AOM, despite the absence of specifically targeted studies.

Those studies that assessed the length of time a child has OME in association with AOM showed that, while antibiotic prophylaxis may reduce the incidence of AOM, it does not reduce the length of time with OME. Therefore, ventilation tubes should be considered for those prone to OME. [Level 1 evidence]

Xylitol

Xylitol is a commonly used sweetener that inhibits pneumococcal growth and the attachment of pneumococci and *Haemophilus* to nasopharyngeal cells. As such, it is a recognized prophylaxis for AOM when administered via chewing gum or syrup. A meta-analysis of limited data revealed significant treatment effects, reducing the incidence of AOM in healthy children attending day care by 25% when given at a dose of 8.4 g/day split into five doses,[25] although this effect was lost when the dose was reduced.[26] The very large quantities that must therefore be consumed and associated compliance issues, as well as lack of information with regards to duration of treatment required and long-term effects of consumption, mean that its use cannot yet be recommended.

Zinc

Zinc is a micronutrient found in a variety of foods and is essential for immune function and resistance to infection. It has been demonstrated to have a beneficial effect in the prevention and treatment of pneumonia and other respiratory conditions, and one study has suggested that zinc levels may be lower in children who experience recurrent AOM than in healthy controls. A meta-analysis examining the efficacy of zinc supplementation on frequency of episodes of AOM in children aged 1–5 years living in low- to middle-income countries showed mixed outcomes with no significant overall effect demonstrated.[27] However, there was limited evidence from one small trial that zinc may reduce otitis media in a cohort of infants being treated for malnutrition.

Vaccination

Vaccines have been used effectively against most common childhood infections caused by single specific organisms such as mumps, measles and rubella. The concept of vaccinating against AOM therefore is an attractive one that is being actively explored. Potential obstacles include the wide range of causative organisms, both bacterial and viral, the varied serotypes, technical difficulties in producing an effective immune response, obtaining an immune response before 6 months of age, parental resistance to multiple vaccination, and the possibility that the successfully targeted pathogens will simply be replaced by others.

Vaccination against viruses

Since 60–90% of episodes are initially associated with viral infections (see above), viral vaccination seems the most logical first step. AOM secondary to infection by the measles virus is now relatively uncommon in industrialized countries, for example.

Influenza A vaccination is currently the only commercially available preparation for the prophylaxis of viral upper respiratory tract infections. However, despite early promising results depicting associated reduced episodes of AOM in vaccinated children, a recent meta-analysis suggests that this reduction is small and that the benefits of vaccination for this purpose may not justify the use.[28] In laboratory-confirmed cases of influenza infection, the use of neuroramidase inhibitors such as oseltamivir has been shown to reduce the incidence of AOM in children aged 1–5 years (risk difference -0.14).[29] However, this is at the expense of increased side effects such as vomiting, and the use of oseltamivir for both treatment and prophylaxis should be carefully considered before commencement. **[Level 1 evidence]**

Respiratory syncytial virus vaccines are yet to demonstrate significant protection against lower respiratory tract infection, and currently recombinant monoclonal antibodies such as palivizumab remain the only way to treat severe respiratory disease secondary to RSV infection.[30] No trials are currently underway assessing a role in AOM.

Parainfluenza virus vaccines are not yet commercially available. Results from Phase 1 trials, however, demonstrate relative safety and immunogenicity in adults and seropositive children although proved insufficiently immunogenic in seronegative children,[31] and the impact on AOM has yet to be explored.

Vaccination against bacteria

Vaccination against *Streptococcus pneumoniae*, nontypeable *Haemophilus influenzae* and *Moraxella catarrhalis* is made difficult by the low immunogenicity of the polysaccharide capsule of these bacteria in young children and infants. Success against *Haemophilus influenzae* type b (which causes epiglottitis and meningitis) using a polysaccharide-protein conjugated vaccine provides one potential solution.

Streptococcus pneumoniae vaccination is particularly challenging because of the 90 different serotypes of the bacteria. However, as only a small number of these cause most pneumococcal AOM, and it has been shown that anticapsular antibodies can prevent pneumococcal AOM, progress has been made. Early attempts with unconjugated pneumococcal polysaccharide vaccines proved unsuccessful in children under 2 years of age. However, polysaccharide-protein conjugate vaccines allowed for an improved immunological response (immunogenic as young as 2 months) and a heptavalent pneumococcal conjugate vaccine (PCV7) was introduced in 2001.

Since the introduction of PCV7 into childhood vaccination schedules, the global burden of pneumococcal diseases in children has significantly reduced. The Centers for Disease Control and Prevention (CDC) reported a 77% reduction in overall invasive pneumococcal disease (IPD) rates and a 98% reduction in PCV7 serotype disease in children aged under 5 years compared with the pre-PCV7 era.[31] In addition, rates of outpatient attendance for recurrent AOM in children under 2 years reduced by 43%, with a 42% reduction in AOM-associated prescriptions in studies in the USA, and the insertion of ventilation tubes for AOM reduced by 16% and 23% in two states.[32] Furthermore, a global reduction in microbial resistance in vaccine serotypes, a reduction in nasal carriage of vaccine serotypes and a reduction in antibiotic resistant serotypes has also been noted.[31]

However, following the introduction of PCV7, the overall serotype distribution altered globally with an observed increase in non-vaccine serotypes. Subsequently, higher-valent pneumococcal conjugate vaccines became available and PCV13 (Prevenar 13®) became part of the UK Childhood Vaccination Schedule in 2010, currently administered at 2, 4, 6 and 12–15 months of age. A decline in IPD was consequently noted in the UK in the additional vaccine-related serotypes with a sustained decline in the original serotype related disease.[31] However, vaccines that confer species-wide protection against multiple bacterial pathogens by utilizing an antigen common to all known types of pneumococci would potentially be able to prevent early bacterial colonization and subsequent recurrent AOM and may prove more successful in the future.

These results are encouraging, but a recent meta-analysis demonstrated that, although PCV7 showed modest beneficial effects on recurrent AOM in healthy infants with a low baseline risk, there appeared to be no benefit in preventing further episodes in high-risk infants and older children who already had a history of AOM,[33] suggesting that prevention of early episodes is critical. Further studies assessing the impact of multivalent PCVs on AOM are ongoing, as are trials into maternal immunization strategies with respect to the benefit to the infant. **[Level 1 evidence]**

Since routine immunization against *Haemophilus influenzae* type b (Hib) was introduced, there has been a marked change in the predominant invasive serotype to non-typeable *Haemophilus influenzae* (NTHi), and the intrinsic heterogeneity of NTHi has led to challenges in

the development of a further successful vaccine. Phase 3 trials have now concluded into the efficacy of a 10-valent pneumococcal vaccine utilizing *Haemophilus influenzae* protein D conjugate (PHiD-CV). Protein D is a lipoprotein of *Haemophilus influenzae* and has produced protection against NTHi in rat and chinchilla models. While efficacy was demonstrated against a broad range of pneumococcal diseases including AOM and showed non-inferiority of PHiD-CV in comparison to PCV7, strong evidence of any additional protective efficacy against NTHi otitis was lacking and several other protein antigens remain under investigation.[34] **[Level 1 evidence]**

Moraxella catarrhalis vaccine research is at a preclinical stage, but the possibility of using surface proteins as vaccine candidates is currently being explored.

Special attention should be drawn to children with or awaiting cochlear implants. Concern has been raised about a potential increased risk of pneumococcal meningitis, although whether it is implant-related or reflects inner ear abnormalities in many of these children is unclear. Most children will receive PCV13 through the Childhood Immunisation Schedule, and it is recommended that children with cochlear implants receive an additional single dose of pneumococcal polysaccharide vaccine (PPV23) after they reach 2 years of age. If the vaccines were not received, or the child was treated with PCV7 only, catch-up doses are recommended up to the age of 18 years. Hib conjugate vaccine is also recommended for all children up to the age of 5 years.[35]

Immunoglobulins

The importance of immunological immaturity in the occurrence of recurrent AOM has been emphasized. However, therapeutic administration of immunoglobulin has produced variable results in clinical trials, and more recent data have contraindicated the dogma that otitis-prone children exhibit specific humoral immunodeficiencies.[36] As such, prophylactic treatment with immunoglobulins has failed to gain momentum.

Benign commensals

Previous data considered whether spraying benign commensals (alpha streptococci) into the nose to recolonize the nasopharynx following antibiotics might reduce AOM by inhibiting the growth of pathogenic bacteria. A significant reduction in recurrent disease and subsequent OME was reported, although failure rates remained high in both groups.[37] However, a separate smaller study, which did not pre-treat with antibiotics, showed no difference and no subsequent research has been performed in this area to date.

SURGICAL PROPHYLAXIS

In contrast to the large number of trials comparing antibiotic treatments, there are relatively few addressing surgical prophylaxis. Surgery is potentially attractive, however, in that it may reduce problems of antibiotic resistance and also treat subsequent OME.

Ventilation tubes

A meta-analysis of five trials concluded that the presence of ventilation tubes versus no tubes yielded a relative decrease in episodes of AOM of 56%, equivalent to an absolute reduction of 1.0 episode per child per year.[38] The effect occurred mostly in the first year of follow-up, presumably as this covered the period when the tubes were in place. Of equal importance is the reduction in the prevalence of OME by 115 days per child-year. Overall 79% were reported to have an improved quality of life. Side effects included recurrent otorrhoea in 7% and chronic otorrhoea in 4%. Other studies have shown a higher incidence of tympanosclerosis and focal areas of tympanic membrane atrophy of questionable significance in the ventilation tube groups.

These findings need careful interpretation. One of the studies compares antibiotic prophylaxis with amoxicillin to tubes to placebo.[39] The amoxicillin group had a significant reduction in episodes of AOM; the tube and placebo group did not. However, when AOM occurred in the placebo group, it was more distressing than when otorrhoea occurred with AOM in the group with tubes in place. Also over a 2-year period the surgical group had 26 and 61 days fewer with OME than the antibiotic and placebo groups respectively.

It is difficult to draw conclusions about the role of ventilation tubes. On the evidence available, they may be considered for children with recurrent AOM but no persistent effusion, in whom medical strategies have failed. There may be a greater role for them in preference to, or following failure of, medical prophylaxis in the child with recurrent AOM and persistent OME. **[Level 1 evidence]**

Adenoidectomy and adenotonsillectomy

The limited evidence base for best practice is most striking when considering adenoidectomy. The theoretical advantage of disrupting possibly pathological biofilms is appealing. Two papers are particularly worth discussing, both with a cohort of children from Pittsburgh. Randomization methods have been questioned in these studies, as has follow-up. The first concluded that adenoidectomy may be beneficial in children who had previously had ventilation tube insertion and suffered subsequent AOM. AOM was reduced by 31% relative to the control group in a 2-year follow-up (or 0.32 episodes per child-year), and subjects spent 42% less time with OME. Additionally, the need for further tubes was reduced by 50%.[40]

The second trial was of children who had not previously had ventilation tube insertion. Considering children without overt adenotonsillar disease, a modest reduction in the number of episodes of AOM was recorded in the first year after surgery from 2.1 to 1.4 following adenotonsillectomy, but not adenoidectomy. Similarly, OME was reduced from 30 to 19 days in year 1 in the adenotonsillectomy group, and to 22 days in the adenoidectomy group. The effect was not apparent after the first year. Dropout from the trial was particularly high in the adenoidectomy group, and the results should

be viewed cautiously. For children with adenotonsillar symptoms no AOM benefit was reported from adenotonsillectomy. The authors concluded the risks of surgery were not warranted in children who had not previously had ventilation tube insertion.

In summary, there is little evidence to support adenotonsillectomy. Adenoidectomy may be considered in those children who have failed medical therapy and had further AOM following ventilation tube insertion. The presence of OME increases the benefit of adenoidectomy.

KEY POINTS

Clinical recommendations for prophylaxis of recurrent acute otitis media

- Modify environmental risk factors.
- Consider antibiotic prophylaxis over the winter months, particularly if there is no background middle ear effusion.
- Vaccination against *Streptococcus pneumoniae* is available.
- Immunoglobulins may have a role in specific deficiencies.
- Consider ventilation tube insertion in the presence of persistent middle ear effusions between acute episodes.
- Consider adenoidectomy in children who have previously had ventilation tubes inserted but have further recurrent episodes of AOM.

OUTCOMES

An episode of AOM may:

- resolve rapidly with or without antibiotics
- prove resistant to first-line antibiotics
- persist or recur shortly after a course of antibiotics has finished
- subsequently recur
- progress to tympanic membrane perforation or other complication of infection.

Here we consider the medium- and long-term consequences of infection: the natural history of AOM, middle ear effusions, auditory functioning, and speech and language development.

Natural history

Data come from the control arms of randomized controlled trials, and hence usually exclude high-risk children, complicated cases, and those under 2 years old. Without antibiotic treatment, symptomatic relief from pain and fever occurs in about 60% of children within 24 hours of diagnosis, in over 80% by day 2–3, and 88% by day 4–7.[9, 41] These data do not equate with complete resolution – for example, otorrhoea may still be present without pain or fever – and only 73% reach the stage of complete resolution by day 7–14. In all studies those with resistant or persistent disease will have received antibiotic treatment.

For recurrent AOM the prognosis is also generally favourable. Following study entry, and with only acute episodes treated, recurrence rates fell to 0.13 episodes per child per month in the subsequent 6–24 months – about 1.6 episodes per year. Indeed, over half had no further attack in the following 6 months, and only 1 in 8 continued to satisfy the diagnostic criteria for recurrent AOM.[41] Other work has shown that, even in early recurrences of infection 3–4 weeks after a previous episode, a new organism is usually involved. Caution should be attached to these findings: though pooled numbers are large, high-risk children and those with baseline OME were generally excluded.

MIDDLE EAR EFFUSIONS

Middle ear effusions are an important outcome of AOM. Looking again at those children randomized to placebo, pooled data show rates of OME of 63% 2 weeks after AOM, 40% at 1 month and 26% at 3 months. Antibiotics did not appear to have any effect.[9, 41]

AUDITORY FUNCTIONING

What little work has been done on short-term audiometric outcomes suggests about 1 in 3 children will have an air–bone gap greater than 20 dB at 1 month after infection, and 1 in 5 at 3 months. There is limited evidence to suggest that AOM may reduce long-term audiometric thresholds. Several studies following cohorts of children have reported small but significant loss of very high-frequency hearing (11–16 KHz) in those with many episodes of AOM. There is a suggestion that this may be more a consequence of disturbed middle ear mechanics than cochlear damage. The significance for auditory functioning as the child grows older is not established.

SPEECH AND LANGUAGE DEVELOPMENT

It is difficult to separate the literature on AOM and OME outcomes. Little is written on speech production or reception. In children with OME a significant effect seems to occur in the early years of life on expressive language development but not receptive language. A small number of studies point to persisting effects on expressive language in school-age children. There is little evidence showing different cognitive development in school-age children with a history of otitis media in the first 3 years of life. There are suggestions that poor behavioural traits may be commoner by school age, but more work is required before conclusions are drawn.

COMPLICATIONS

Extracranial complications

TYMPANIC MEMBRANE

Tympanic membrane perforation is considered a complication of AOM. It is the commonest complication of infection

and is reported in 0–10% of episodes. Perforation is associated with a purulent or bloody otorrhoea and immediate relief of pain. It typically occurs in the posterior half of the pars tensa, and is associated with loss of the fibrous middle layer of the drum. This may predispose to future posterior retraction pockets. Four outcomes of perforation may result:

- In most cases the perforation heals spontaneously and the infection resolves.
- The infection may resolve but the perforation may persist. This may predispose the ear to future AOM or chronic suppurative otitis media.
- The perforation and otorrhoea may persist, manifesting as chronic suppurative otitis media. 'Chronicity' is generally deemed to have occurred by 3 months.
- A further complication may arise.

Haemophilus influenzae is the dominant otopathogen cultured in AOM with tympanic membrane perforation (followed by *Streptococcus pneumoniae*, then *Moraxella catarrhalis*). In an animal model, addition of dexamethasone to topical treatment with antibiotic drops significantly impaired short-term healing of perforation (at 4 weeks). The location and size of the perforation correlates to the resulting degree of sound conduction impairment, with larger perforations and those located in the anteroinferior quadrant leading to a larger conductive deficit.[42]

The long-term outcomes were assessed in a cohort of otitis-prone children followed up from 3–14 years of age. By the end of the study 7% had collapse of the posterior superior tympanic membrane, chronic suppurative otitis media, or central perforation.[43] Scarring or tympanosclerosis was present in 27%, though several studies report that ventilation tubes increase this risk.

ACUTE MASTOIDITIS

Four classes of mastoiditis are defined. During episodes of **acute otitis media** infection and inflammation may naturally extend into the mastoid cavity and be visualized radiologically. This is not associated with the typical signs of acute mastoiditis and is not considered a complication of AOM.

Infection may spread to the mastoid periosteum by emissary veins: **acute mastoiditis with periosteitis**. At this stage no abscess is present but the postauricular crease may be full, the pinna may be pushed forward, and there may be mild swelling, erythema and tenderness of the postaural region.

When **acute mastoid osteitis** develops, the infection has begun to destroy the bone of the mastoid air cells, and a subperiosteal abscess may develop. Signs may be similar to those when periosteitis is present. A subperiosteal abscess develops most commonly in the postauricular region. A zygomatic abscess may develop above and in front of the pinna. A Bezold abscess may result from perforation of the medial mastoid cortex, tracking down sternomastoid to the posterior triangle. Pus tracking down peritubal cells may result in a retropharyngeal or parapharyngeal abscess.

A fourth stage may be reached, **subacute ('masked') mastoiditis**, in incompletely treated AOM after 10–14 days of infection. Signs may be absent but otalgia and fever persist. This stage can also progress to serious complications.[3]

In the pre-antibiotic era mastoiditis was a common and serious complication of AOM. In a study in 1954 the control group were reported to have developed mastoiditis in 17% of cases.[9] In some developing countries rates of 5% are still quoted. In the 1970s it was estimated that 0.004% of cases of AOM resulted in surgery for mastoiditis. Many papers reported a drop in the incidence of pneumococcal mastoiditis following the introduction of the pneumococcal conjugate vaccine, however the incidence subsequently rose to parallel pre-PCV7 levels, postulated to be secondary to an increase in replacement serotypes. A recent paper showed, however, that the levels of pneumoccocal mastoiditis did not drop again as expected with the introduction of PCV13.[44] The current incidence is estimated to be around 1.2–6.1 cases per 100 000 inhabitants in developed countries.[45]

Acute mastoiditis is a disease of childhood. A large multicentre study found 28% to be in children less than 1 year of age, 38% 1–4 years, 21% 4–8 years, 8% 8–18 years, and 4% over 18 years old.[46] This higher incidence in younger children reflects the peak ages for AOM. Children under 2 years of age also show more distinct clinical signs of mastoiditis and higher inflammatory markers than older children, but they exhibit a more rapid improvement of symptoms, with lower rates of complications and surgery.[47]

Traditional teaching was that acute mastoiditis is preceded by 10–14 days of middle ear symptoms. However, in many papers the short length of middle ear symptoms prior to presentation is noteworthy. For example, in one large study about 32% had 1–2 days of symptoms, 34% had 3–6 days, 26% 7–14 days, and 8% over 14 days.[46] Prior antibiotic treatment of the infection is common, reported in 22–55% of children. Studies have shown that, despite reducing overall prescription rates for AOM, the incidence of acute mastoiditis has remained stable, with no significant difference demonstrated in prior antibiotic use between those who developed a subperiosteal abscess and those who did not.[48] It is therefore clear that antibiotics do not fully protect against mastoiditis.

Symptoms are of otalgia and irritability in most children. Diagnosis usually rests on the presence of postauricular swelling, present in 80–95% of cases, and protrusion of the pinna, seen in 95–100%.[49] Postauricular erythema and tenderness are also usually present and typically sited over MacEwen's triangle (on palpation through the conchal bowl). Pyrexia is reported in around 81% but is less common in those treated with antibiotics. Otorrhoea is present in only about 30%. Clinically, a red or bulging tympanic membrane will often be seen. A normal drum is reported in a very variable proportion of cases, but certainly does not exclude the diagnosis, and is believed to result from resolution of the mesotympanic infection following antibiotic treatment while the osteitis in the mastoid progresses. Sagging of the posterior wall of the

external auditory canal, resulting from subperiosteal abscess formation, should be looked for but is quoted as an uncommon finding. Few patients will have a 'full house' of the classic signs, and 22% may have no clinical symptoms prior to protrusion of the ear.

A somewhat different incidence of organisms has been identified from those gained from culture in AOM. Around 20% of samples do not grow bacteria. *Streptococcus pneumoniae*, *Streptococcus pyogenes*, *Pseudomonas aeruginosa* and *Staphylococcus aureus* are the most commonly reported in order of decreasing frequency. *Haemophilus influenzae* is less commonly reported, and *Moraxella catarrhalis*, *Proteus mirabilis* and Gram-negative anaerobes rarely. *Fusobacterium necrophorum* is also being increasingly implicated. Clinical features may vary in accordance with the pathogen isolated. *Streptococcus pneumoniae* appears to lead to more severe symptoms and a higher incidence of mastoidectomy, *S. pyogenes* causes less otalgia and *Pseudomonas aeruginosa* particularly affects children with ventilation tubes, with a less aggressive clinical course.[50]

Recommended investigations vary between institutions. A full blood count, CRP and blood cultures are often obtained. A CT scan of the mastoid is recommended when intracranial complications are present or suspected (though MRI may be more helpful in identifying specific intracranial pathology), when mastoidectomy is to be performed, and in those not improving on antibiotic treatment. A CT scan may show evidence of osteitis, abscesses and intracranial complications.

Differential diagnosis includes AOM, otitis externa, furunculosis and reactive lymphadenopathy. Rarely, undiagnosed cholesteatoma, Wegener's granulomatosis, leukaemia and histiocytosis may first present with AOM, hence tissue should be sent for histology if mastoidectomy is performed.

Although simple mastoidectomy represents the most reliable and effective surgical method to treat acute mastoiditis, a more conservative approach consisting of adequate parenteral antibiotic coverage with or without myringotomy is being increasingly adopted for children suffering from uncomplicated acute mastoiditis. The antibiotic of choice is generally a third-generation cephalosporin, or an aminopenicillin combined with a β-lactamase inhibitor. If *Pseudomonas aeruginosa* is suspected, treatment should include ciprofloxacin, piperacillin or fosfomycin.[45] Cases where there is a suspicion of intracranial complication and those not responding to conservative treatment should undergo cortical mastoidectomy. This may be combined with myringotomy with or without ventilation tube placement, and culture of the aspirate. This can be challenging surgery for the less experienced as the mastoid is often full of granulations and the facial nerve superficial in the young child. There is no uniformity in the literature as to the appropriate duration of observation prior to proceeding with surgery, with authors recommending periods in the wide range of 24–72 hours. The presence of a subperiosteal abscess, an unwell child, or a deteriorating clinical picture should prompt more rapid intervention. If in doubt, it is our recommendation to intervene to prevent complication, and sooner rather than later.

A most important message is that intracranial complications from acute mastoiditis develop in 6–17% of cases, and many of these may develop during hospitalization. Although acute mastoiditis may be less common than in the past, its severe complications still occur.

PETROSITIS

Infection may extend to the petrous apex. The classic features of Gradenigo's triad (VI nerve palsy, severe pain in the trigeminal nerve distribution and middle ear infection) are not always present. Patients commonly present with other intracranial complications. Historically, the treatment has been surgical, with a minimum of drainage of the mastoid and, in some centres, decompression of the petrous apex. Resolution of the sixth nerve palsy follows a variable course, from almost instant recovery to taking up to 6 weeks. However, more recently many patients have been successfully managed conservatively with administration of parenteral antibiotics, and most would now reserve surgery for those not responding to conservative management. Sixth nerve palsy resolution with conservative treatment can take up to 3 months.[51]

FACIAL NERVE PALSY

In the pre-antibiotic era it was estimated that acute lower motor neuron facial palsy complicated 0.5% of episodes of AOM. It is now quoted at 0.005%.[52] Most are related to bacterial infection, with one review suggesting the majority are secondary to *Staphylococcus aureus*, but case reports with viral AOM exist. The pathophysiology in most cases is a neuropraxia secondary to oedema or nerve compression, or to bacterial toxic metabolites in the setting of a congenitally dehiscent facial nerve. About four out of five children present with a partial paralysis. The case series in the literature report that about 80% of palsies respond well to ventilation tube insertion and intravenous antibiotics. The remainder undergo cortical mastoidectomy. Corticosteroids are also often used although there is no strong evidence base to support their use. Advice is conflicting about when and in whom mastoidectomy is required and the role of facial nerve decompression, although as recovery is generally so good, a more conservative approach without facial nerve decompression seems appropriate.

Some authors would advocate early electrophysiological testing in all patients with a complete paralysis as recovery in these cases can be more variable, with surgical intervention limited to those who fail conservative treatment or exhibit poor electrophysiological testing.[53] Most children achieve rapid restoration of normal facial function, with a mean time to complete recovery of 4 months. Those with a total paralysis at presentation have a recovery stretching over many months.

Sixth nerve palsy in the absence of petrositis has also been reported. It is speculated this may stem from phlebitis spreading along the inferior petrosal sinus from the lateral sinus.

LABYRINTHITIS

Round window permeability changes during acute infection are important as these may allow entry of bacterial toxins. There is some experimental evidence that permeability can be increased by streptococcal toxins. Preformed channels for bacterial entry may also exist, such as surgical or congenital perilymph fistulae. These may allow infection to spread directly to the subarachnoid space causing meningitis. Particular concern arises in children with congenital inner ear abnormalities, and those with cochlear implants.

Three types of labyrinthitis are recognized. **Perilabyrinthitis** is not associated with AOM. **Serous labyrinthitis** is inflammation of the labyrinth without pus formation, characterized by sensorineural hearing loss and vertigo, usually in a non-toxic patient. There may be an additional conductive loss secondary to the presence of fluid. Typically there is complete and rapid recovery of auditory and vestibular function.

Suppurative labyrinthitis may result from spread of infection from the mastoid or middle ear and may raise the suspicion of an anatomical defect or immune deficiency. Severe vertigo, nausea, vomiting, nystagmus and permanent hearing loss result. The nystagmus may exhibit various patterns, possibly due to differential effects on inner ear function by toxic or inflammatory mediators, however direction-fixed, irritative-type is the most common observed pattern.[54] Suppurative labyrinthitis is rare, and diagnosis is usually made based on clinical and audiometric findings. MRI, if performed, may demonstrate contrast enhancement of the labyrinth and there is some evidence to suggest the degree of enhancement correlates to both subjective symptoms and objective assessment of nystagmus. CT is not helpful in diagnosis but may help to delineate underlying anatomical abnormalities.[53]

The treatment of cases presented in the literature ranges from ventilation tube insertion and aggressive antibiotic use, to tympanomastoidectomy and cochleotomy. Resolution of the vertigo may take weeks to months to occur, demonstrating contralateral vestibular system compensation rather than recovery of function of the affected ear. Longer-term complications of suppurative labyrinthitis may include labyrinthitis ossificans, caused by fibrous or bony replacement of the labyrinth. The administration of steroids during the initial phase of the illness may help prevent the development of this complication.[53]

Intracranial complications

In the pre-antibiotic era intracranial complications of AOM were more common and mortality rates of over 75% are presented. Published mortality rates from intracranial complications now average about 5% in industrialized countries. Estimates of the incidence of intracranial complications vary significantly in the literature, with figures ranging from 0.04% to 17.6%.

The most common symptoms associated with an intracranial complication include fever, otalgia, cephalgia and reduced general condition as well as altered mental status. In other words, do not ignore the child with a headache, pyrexia and ear infection. In half of cases there may be signs only of AOM, and not mastoiditis. Frequently two or more complications coexist. Early diagnosis is important for improving outcomes. As the clinical picture in some cases may not differ from that of acute mastoiditis in terms of signs, symptoms and inflammatory indices, the clinician should always remain alert to the possibility of an otherwise asymptomatic intracranial complication and maintain a low threshold for performing imaging studies. CT with intravenous contrast is the usual imaging technique of choice for patients with acute mastoiditis as this also provides a road map for surgery. MRI is the preferred imaging modality in the presence of suspicion of intracranial complications, as it is superior to CT in the identification of intracranial suppurative lesions, meningeal enhancement and extradural granulation tissue. However, the difficulty in children under 7 years of age is that they are likely to require a general anaesthetic for this so a discussion with the parents regarding the risk and reward of different imaging modalities may be required. MR venography may be utilized to demonstrate the degree of patency of the associated venous sinuses.

Seven classical intracranial suppurative complications of AOM are described:[3] meningitis, extradural abscess, subdural empyema, sinus thrombosis, cerebritis, brain abscess and otitic hydrocephalus.

MENINGITIS

Meningitis is usually cited as the commonest intracranial complication of AOM, accounting for 54–91% of cases. In contrast, studies assessing aetiology of meningitis are conflicting. One of the largest recent studies found no association between bacterial meningitis and AOM, while another found an antecedent history of AOM in 29%,[55] though this does not equate to a causal relationship. The earliest symptoms are headache, fever, vomiting, photophobia, irritability and restlessness, with fullness of the anterior fontanelle in children under 22 months of age. Diagnosis is usually made on the clinical presentation, with a lumbar puncture demonstrating white blood cells and low glucose in the CSF. Special mention has already been made of possible associations between congenital inner ear malformations such as cochlear dysplasia and cochlear implants, and meningitis. Younger children, average age 2 years, are most commonly infected.

Studies focus almost exclusively on bacterial aetiologies. The rate of *Haemophilus influenzae* type b meningitis has dropped dramatically since vaccination was introduced. *Streptococcus pneumoniae* is the causal agent in a greater proportion because of this reduction.[55] A second intracranial complication should be looked for in any infant with meningitis with MRI scanning and the presence of a lung focus has been identified an as independent prognostic factor for an unfavourable outcome.[56] Myringotomy may help establish the infective agent if evidence has not been obtained from lumbar puncture.

Treatment is medical and should comprise a third-generation cephalosporin with consideration given to the

addition of vancomycin to cover for resistant strains. Some papers suggest that addition of dexamethasone may reduce potential neurological sequelae, although this appears to have no effect on audiological outcome which can affect 16% of children.[57] If mastoid surgery is required, it is usual to wait for an improvement in the medical condition of the child first if possible.

EXTRADURAL ABSCESS

This is the next commonest intracranial complication. It is more commonly associated with chronic disease. Pus collects between dura and bone, usually after bone erosion. If this lies in the posterior fossa medial to the sigmoid sinus, it is termed an extradural (epidural) abscess; if it is within the split of dura enclosing the sigmoid sinus, it is called a perisinus abscess. It may be discovered only at mastoidectomy, but may be suspected in the patient with persistent headache and fever, or severe otalgia. Treatment is surgical drainage.

SUBDURAL EMPYEMA

A collection of pus between the dura and arachnoid membranes is termed a subdural empyema. It is rare. It develops by direct extension of infection or thrombophlebitis. In addition to headaches and pyrexia, focal neurological signs, seizures and signs of meningeal irritation may be present. Paranasal sinusitis is reported to be a much commoner cause than AOM. Surgical drainage of the abscess through burr holes or craniectomy may be indicated. Mastoidectomy may sometimes be required, though many cases cited in the literature were treated medically.

SIGMOID SINUS THROMBOSIS

This has an estimated incidence of 0–2.7%[58] and most commonly results from erosion of the bone over the sinus from mastoiditis, and may also be associated with other complications. However, it occurs in association with otitis media alone in 43% of cases. Infected thrombus develops within the sinus and may then extend proximally and distally to the internal jugular vein and superior vena cava, entering the systemic circulation and causing septicaemia. In addition to headache and otorrhoea, a spiking pyrexia may develop. Griesinger's sign is mastoid tenderness and oedema secondary to thrombophlebitis of the mastoid emmisary vein. The presence of specific neurological signs and symptoms is significantly correlated with hypoplasia of the contralateral venous sinus and may be absent in up to 50% of children. The presence of *Fusobacterium necrophorum* dictates a more aggressive and prolonged clinical course. MRI is the imaging of choice showing an acute clot as isodense on T1 and hypodense on T2, with a subacute clot becoming hyperintense on T1. The addition of MR venography will demonstrate lack of flow and increase the sensitivity of the diagnosis especially in the early stage.

Management options described in the literature invariably include the use of systemic broad-spectrum antimicrobials. Non-pneumococcal streptococcal, anaerobic and staphylococcal species are commonly implicated and therefore ceftriaxone, metronidazole or clindamycin are commonly used.[59]

The surgical approach varies dramatically in the literature from myringotomy with ventilation tube placement, to mastoidectomy with or without delamination of the sigmoid sinus, needling of the sinus or thrombectomy. Internal jugular vein ligation and craniotomy have also been described.

The use of post-operative anticoagulation also varies between institutions, with duration ranging from 6 weeks to 6 months. Only one study reported an episode of a subsequent non-life-threatening intracranial haemorrhage, with no other complications related to the treatment identified in any of the other studies, leading to the conclusion that anticoagulation was safe if administered correctly.[60] The current British Society of Haematology guidelines for the management of paediatric cerebral venous sinus thrombosis recommends that anticoagulation should be commenced if there is no associated intracranial haemorrhage. This recommendation is, however, based on a non-significant trend in the anticoagulated group towards better survival and cognitive outcome, and the recommendation is not specific to venous sinus thrombosis of otological origin.[58] At least one series has shown unusually high rates of prothrombotic factors in children with otogenic venous sinus thrombosis, and it has therefore been suggested that anticoagulation may be used selectively in appropriately screened individuals, with a lower threshold for treatment in those in whom there is evidence of thrombus extension, such as Lemierre's syndrome.[59] A multidisciplinary approach with the involvement of paediatricians, haematologists and the infectious diseases team is recommended. In non-anticoagulated cases, it is recommended that further imaging is performed to look for evidence of extension of thrombus.

A recent systematic review into the management of otogenic paediatric cerebral venous sinus thrombosis found that 92% of patients underwent some form of surgery. Just over two-thirds of these patients underwent 'conservative surgery', most commonly mastoidectomy with decompression of the bony covering of the venous sinus. The remainder underwent a more extensive operation, usually mastoidectomy with thrombectomy, with IJV ligation performed in just 6%. Anticoagulation was the treatment for 59%, and a non-life-threatening bleeding-related complication such as post-operative haematoma was reported in 7%. A good outcome was reported in 79%. For those undergoing follow-up scans, complete recanalization was observed in 51% overall occurring up to 5 months later (47% of those who had been anticoagulated and 55% of those who had not).[58] Conservative surgery with anticoagulation is the most common treatment modality administered at present, although the low level of evidence available hinders the development of truly evidence-based guidelines.

FOCAL OTITIC ENCEPHALITIS (CEREBRITIS)

Focal inflammation and oedema of brain tissue may occur independent of or in association with any suppurative complication of AOM. Intensive antibiotic treatment is required.

BRAIN ABSCESS

Brain abscesses are more commonly associated with chronic ear disease but may occur in association with AOM and its complications. They form a larger proportion of complications in developing countries. They develop in both the temporal lobe and cerebellum. In the setting of acute mastoiditis, the most common causative organism is *S. pneumoniae* or other non-pneumococcal *Streptococcus* species.[59] Persistent headaches are the commonest symptom. Initial symptoms may be of encephalitis, but these often settle as the abscess organizes over days or weeks. Eventually, signs of raised intracranial pressure, focal neurology and infection develop. Investigations include CT imaging followed by lumbar puncture if safe.

Patients should undergo treatment with broad-spectrum antibiotics and mastoidectomy to remove the infective foci. In the early stages of cerebritis neurosurgical drainage may be avoided, but it will be required if the abscesses are expanding. Brain abscesses carry a potentially high mortality rate, though in industrialized countries the few large series now quote rates of below 10%. One large review found the mortality from otogenic causes, at 3.8%, was much lower than from other causes. The presence of morbidity such as sensorineural hearing loss, vestibular dysfunction and neurological sequelae varies from 20% to 79% and is reduced with early intervention and treatment.

OTITIC HYDROCEPHALUS

This is a complication of AOM manifesting as raised intracranial pressure in the absence of any space-occupying lesion, and without obstruction to the flow of CSF. Benign intracranial hypertension is a synonym. The aetiology is obscure. Headache is the predominant symptom and may be associated with drowsiness, vomiting, visual disturbance and diplopia, with signs of papilloedema and abducens nerve palsy on examination. It is commonly associated with sigmoid or transverse sinus thrombosis and so MRI/MRV are important investigations. Lumbar puncture will show raised CSF pressure, but normal CSF composition.

A number of medical treatments may be tried such as corticosteroids, mannitol, diuretics and acetazolamide and liaison with a paediatric neurologist is recommended.

CONCLUSION

It can be seen from this chapter that there are deficiencies in our current knowledge of both the diagnosis and aetiology of AOM, and uncertainties in management strategies. We have, however, been able to describe a number of potentially exciting developments that have occurred in the past few years. ‘Future research’ below summarizes what we feel this chapter should be able to report on when the next edition is being prepared.

BEST CLINICAL PRACTICE

- ✓ AOM is one of the commonest illnesses of childhood. Accurate diagnosis is notoriously difficult. A high index of suspicion is required in the unwell child.
- ✓ The clinician should distinguish between sporadic, resistant, persistent or recurrent AOM as management strategies differ. **[Grade A]**
- ✓ Two-thirds of children recover within 24 hours with or without treatment, so a period of watchful waiting may be reasonable in uncomplicated AOM. **[Grade A]**
- ✓ Antibiotics should not be withheld in severe or irregular infections, should be given if a child fails to improve within 2–3 days of the onset of AOM, and should be given in sufficiently high doses. **[Grade A]**
- ✓ Pyrexia (>37.5 °C), severe otalgia, vomiting, age under 2 years, and ‘high-risk’ children have all been used as indicators to use antibiotics sooner rather than later.
- ✓ Practitioners should be aware of local bacterial antibiotic resistance patterns, and prescribing policies. Broad spectrum antibiotics are not generally required as first line therapy. **[Grade A]**
- ✓ In otherwise healthy children over 2 years of age, 5 days antibiotics are usually adequate. **[Grade A]**
- ✓ For persistent or resistant AOM it should be noted that while pneumococcal drug resistance can usually be overcome by increased antibiotic doses, *Haemophilus* may be beta-lactam producing, so broader spectrum antibiotics may be required.
- ✓ Modifiable risk factors should be discussed with parents. These include nursery attendance, parental smoking, breast feeding, and the use of pacifiers.
- ✓ In the management of recurrent AOM, 8 months of antibiotic prophylaxis would on average be needed to prevent one episode of AOM. This strategy may be preferred in the absence of effusions between episodes of AOM. **[Grade A]**
- ✓ Ventilation tube insertion reduces the number of episodes of AOM by over 50%. This option may be preferred when effusions persist between episodes of AOM. **[Grade A]**
- ✓ Additional adenoidectomy may further reduce the number of episodes of AOM. **[Grade A]**
- ✓ The benefits of tonsillectomy on episodes of AOM are not sufficient to warrant its use in the management of recurrent AOM. **[Grade A]**
- ✓ Vigilance should be maintained for complications of AOM, the commonest symptoms being persistent pyrexia and headache.

FUTURE RESEARCH

- Greater standardization and reproducibility of diagnostic criteria is required to compare trials.
- The role of biofilms in the aetiology and treatment of middle ear infection is under intensive study.
- As most children appear to recover without treatment, better characterization of those who may have initial antibiotic treatment withheld is needed.
- Trials should be set up to study high-risk groups of children who are currently excluded from most studies: those with conditions predisposing them to acute otitis media; and children under 18 months of age. These are the children likely to benefit most from our intervention.
- Vaccination has been shown to be beneficial. Broadening the role for vaccination is likely over the next decade.
- The number and quality of trials of surgical intervention do not allow confident guidance to be given as to the long-term benefits, or consequences, of ventilation tube insertion.
- More data are required on the long-term consequences of recurrent infection in terms of altered audiometric thresholds, quality of life, and language and cognitive development.

KEY POINTS

- Acute otitis media is one of the commonest illnesses of childhood.
- Diagnosis can be difficult, particularly in very young children.
- Management recommendations vary widely between countries.
- A range of modifiable risk factors should be addressed.
- Evidence is emerging to support new prophylactic strategies.
- Intracranial complications are still seen despite prior antibiotic treatment.
- Do not ignore the child with AOM, headache and pyrexia.

ACKNOWLEDGEMENT

The authors would like to acknowledge the great contribution that Mr John Graham, consultant ENT Surgeon, made to this chapter in the previous edition.

CHAPTER 15

CHRONIC OTITIS MEDIA

William P.L. Hellier

SEARCH STRATEGY

Data in this chapter may be updated by a PubMed search using the following keywords: chronic otitis media, chronic suppurative otitis media, cholesteatoma, paediatric, children, residual cholesteatoma and reccurent cholesteatoma.

INTRODUCTION

Traditionally, the term chronic suppurative otitis media (CSOM) describes chronic middle ear (ME) disease and is defined as 'chronic inflammation of the middle ear and mastoid cavity, which presents with recurrent ear discharge or otorrhoea through a tympanic membrane perforation'.[1] Chronic inflammation and changes within the ME cleft are, however, not necessarily associated with a non-intact eardrum. The term chronic otitis media (COM) is a better term to encompass the varied pathology seen as a result of chronic ME inflammation. COM was previously considered a direct result of acute otitis media. It is now suggested that, although COM can certainly be precipitated by an acute infection with or without tympanic membrane perforation, it may occur without episodes of acute otitis media.

Histologically, the findings in COM are similar to the initial changes in acute otitis media (AOM) with mucosal and submucosal inflammation (see Chapter 14, Acute otitis media). Continuing inflammation leads to a submucosal infiltrate with histiocytes, lymphocytes and other mononuclear cells, increasing vascularity, and an increase in mucous-secreting goblet cells. The chronic inflammation can lead to osteitis with bone destruction in or around the ME cleft. The ear responds with attempts at healing and repair. This can lead to the florid vascular granulation tissue that may form aural polyps, and the formation of new bone. Inflammation or infection can spread outside the middle ear or temporal bone leading to the complications of COM.

If the ongoing inflammation does resolve, either due to the body's response or because of medical or surgical intervention, the changes left by the chronic inflammation may persist. Submucosal scarring and fibrosis, increased mucous-producing cells, bony erosion or new bone growth, perforation or thinning of the tympanic membrane and changes in the labyrinth can all be seen. It is useful, therefore, to divide COM into **active COM** (ongoing chronic inflammation) and **inactive or healed COM**, where the chronic inflammation has resolved due to time or medical/surgical intervention but sequelae may still be present.

COM causes a variety of pathological changes that are recognized clinically. Generally, COM can be divided into **COM with cholesteatoma** and **COM without cholesteatoma**.

COM without cholesteatoma includes tympanic membrane changes including perforation, tympanosclerosis, thinning or atrophy of the drum, ossicular changes including erosion or fixation and the mucosal changes as described above. These conditions and their treatment are dealt with in Chapter 83, Chronic otitis media. This chapter will consider COM with cholesteatoma.

COM WITH CHOLESTEATOMA

Muller in 1838 first used the term 'cholesteatoma' describing what he thought was a neoplastic lesion with keratin flakes appearing to look like cholesterol crystals. Despite its 'oma' suffix, cholesteatoma is not a true neoplasm, even taking account of the propensity for the keratin epithelium to accumulate and invade the middle ear and mastoid and to erode the temporal bone. A recent consensus definition is: 'Cholesteatoma is a mass formed by keratinizing squamous epithelium in the middle ear and/or mastoid, subepithelial connective tissue and by the progressive accumulation of keratin debris with/without surrounding inflammatory reaction'.[2]

Paediatric cholesteatoma can be divided into congenital and acquired types.

Congenital cholesteatoma

Congenital cholesteatoma (CC) is 'an expanding cystic mass with keratinizing squamous epithelium located medially to the intact tympanic membrane, assumed to be present at birth but usually diagnosed during infancy or in early childhood in patients with no prior history of otorrhea, perforation, or previous ear surgery'.[2] The most accepted aetiology for the cause of CC is the persistence of epidermoid cell rests found in the anterior part of the epitympanum.[3] These rests are thought to usually regress but, if they persist and grow, squamous epithelium accumulates in the ME space forming a CC. Most CC seems to arise from the anterior ME[4] as a defined sac of epithelium, which would fit with this theory. CC is also found purely arising in the posterior ME or elsewhere in the temporal bone, so there may be other cell rests or there may be another pathogeneses. CC can also be found in the ME as free keratin epithelium with no defined sac.[5]

Petrous apex cholesteatomas, with cholesteatoma in the deep temporal bone with no obvious connection to the ME, are also thought to be caused by congenital rests of epithelium. They represent a different spectrum of disease and are discussed elsewhere (see Chapter 108).

To make a diagnosis of CC most definitions describe that there should be no history of AOM or tympanic membrane perforation, and the drum should be intact. However, AOM is common in the paediatric population, and it has been suggested that infrequent episodes of AOM should not exclude the diagnosis of CC. Late diagnosis of a CC can occur if there are few symptoms in the early stages. An extensive CC can become infected, leading to breakdown of the drum and a perforation, which is seen at the initial presentation. It can therefore be difficult in an older child to be sure whether their cholesteatoma is congenital or acquired.

There have been a number of staging systems suggested for CC, based on the extent of spread of keratin epithelium in the ME. Potsic[6] described a four-point staging system according to the degree of cholesteatoma spread in the ME, from his experience with treatment of 160 CCs:

Stage I	Single quadrant, no ossicular involvement or mastoid extension
Stage II	Multiple quadrants: no ossicular involvement or mastoid extension
Stage III	Ossicular involvement: includes erosion of the ossicles and surgical removal for eradication of disease; no mastoid involvement
Stage IV	Mastoid extension (regardless of findings elsewhere).

The stage of the CC at presentation was directly related to the risk of residual disease post-surgery (see later), and to the degree of initial hearing loss. There are other CC staging systems, such as the one described by Nelson.[4]

Acquired cholesteatoma

Acquired cholesteatoma (AC) in children is similar to adult disease in terms of its definition and aetiology. AC is not present at birth but develops with keratin epithelium invading the middle ear and temporal bone. Acquired cholesteatomas may be classified as being primary or secondary.

Secondary acquired cholesteatoma may develop due to ingrowth of keratin epithelium associated with a tympanic membrane perforation as a result of acute perforation or due to ear trauma of various types. More severe trauma, such as temporal bone fractures, can lead to keratin implantation within the ME or mastoid. Iatrogenic implantation of squamous epithelium can also occur after surgery. Any procedure where the ME is entered, even grommet insertion, can allow keratin epithelium to be left in the ME and the development of cholesteatoma.

The exact pathogenesis of **Primary acquired cholesteatoma** is debated, but four main mechanisms are proposed:

- the metaplasia theory
- the retraction theory
- the immigration theory
- the basal hyperplasia or papillary ingrowth theory.

A number of these factors working together may be responsible for cholesteatoma formation (e.g. retraction and basal hyperplasia).[7] These are discussed in more detail in Chapter 82, Acute otitis media and otitis media with effusion in adults.

The most commonly accepted theory is the retraction theory, which postulates that there is ingrowth of the squamous epithelium of the eardrum into the middle ear due to retraction of either a normal or an atrophic tympanic membrane.

Retraction of either the pars tensa or pars flaccida can occur, and this process is thought to be a sequel of dysfunction of the regulation of middle ear pressure. When the squamous epithelium in the retraction can no longer migrate out and 'self-clean', keratin debris builds up in the middle ear leading to slow invasion.

There are a number of theories regarding failure of the maintenance of normal middle ear pressure. The most widely accepted is that there is dysfunction of the Eustachian tube, leading to hypoventilation of the ME and a negative ME pressure. This negative ME pressure acts on either a normal or, if there has been AOM

or COM, an atrophic or thinned tympanic membrane, causing it to retract and allow cholesteatoma formation. Experimental animal models have shown that obstruction of the Eustachian tube causes drum retractions.[8] Children who have a cleft palate are found to have a higher incidence of cholesteatoma.[9, 10] Children are well recognized to have relatively poor Eustachian tube function, witnessed by their high rates of AOM and OME.

Epidemiology

The exact incidence of cholesteatoma in children is hard to know precisely and may vary between different races. A number of series from a variety of countries give different figures. A Danish study[11] gives the incidence as 8–15 per 100 000 person-years between 1977 and 2010. Earlier studies estimated incidence in the USA as 6 per 100 000 children.[9] Other studies have estimated the incidence as between 3 and 15 cases per 100 000 children.[12–15] Caucasians and African populations seem to have the highest cholesteatoma prevalence of all, with a low rate in non-Indian Asians and the Inuits.[16–18]

In approximately 7–10% of children there may be bilateral cholesteatomas at presentation, or contralateral cholesteatoma may develop during follow-up.[19, 20]

Congenital cholesteatoma has been calculated to make up approximately 10–28% of paediatric cholesteatoma, with 2–3% being bilateral (**Figure 15.1**).[4, 6, 21, 22]

Nelson et al.[4] found that children with CC tend to present earlier (5.6 +/– 2.8 years) than those with acquired cholesteatoma (9.7 +/– 3.3 years). Other authors have found a mean age for surgery for paediatric cholesteatoma to be around 10 years.[23, 24] Most studies on the epidemiology of paediatric cholesteatoma are based on surgical series.

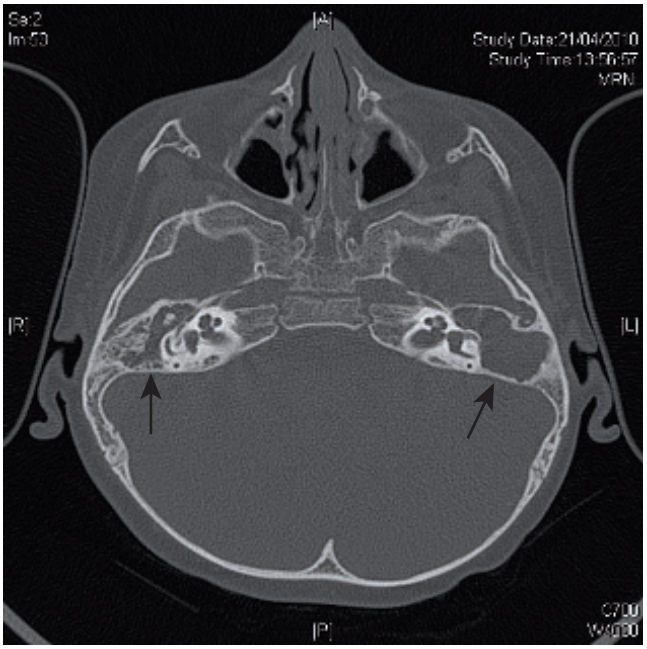

Figure 15.1 Axial CT scan in a 5-year-old child. Arrows show mastoid opacification on both sides due to bilateral cholesteatoma, with erosion of the lateral semicircular canal on the left.

There is some evidence[10, 25] that the use of ventilation tubes may lead to a decrease in the incidence of paediatric cholesteatoma, probably due to the improvement of Eustachian tube dysfunction (ETD) and reducing the negative ME pressure that may cause the tympanic membrane retraction process.

DIFFERENCES BETWEEN PAEDIATRIC AND ADULT CHOLESTEATOMA

There are many similarities between adult and paediatric cholesteatoma: the nature of the disease process, the microscopic pathological findings and certain options for treatment. There are differences in terms of cholesteatoma origin (especially in CC), the areas of the temporal bone affected, temporal bone anatomy, some treatment limitations, the rates of residual and recurrent disease and the extent of ongoing Eustachian tube dysfunction. CC more commonly arises from the anterior middle ear, and therefore will often completely fill the ME cleft, including the Eustachian tube orifice, before spreading to the attic and mastoid. Paediatric cholesteatoma (PC) in general seems to spread more extensively through the temporal bone than in adult disease on average, with more involvement of the peri-labyrinthine cells and petrous apex.

There have been suggestions that PC is more aggressive than adult cholesteatoma, but there is no definitive proof that this is the case. The paediatric temporal bone is often more pneumatized than the adult's, so it is possible that the pathways through which cholesteatoma can invade are more open and the process of spread is easier,[26–29] leading to more extensive disease at presentation. Some studies have reported a greater inflammatory response in PC than in adult cholesteatoma, with an increased expression of various markers including metalloproteinases and certain antibodies.[28, 30–34] Greater inflammation, if present, may well lead to more bone erosion and spread of the squamous epithelium.

When compared to adult cholesteatoma, PC does not seem to invade the petrous labyrinth in as many cases. The rate of lateral semicircular canal (LSCC) fistula is less than in adults, as is erosion of the Fallopian canal and exposure of the facial nerve.[28, 35–39] Ossicular erosion due to cholesteatoma, however, seems to be more common in children.

In the child, the function of the Eustachian tube is often poor. Middle ear disorders such as AOM and OME are far more common in children than adults. The immaturity of the ET and the negative ME pressure it produces is one of the likely aetiological factors for the development of cholesteatoma. In adults, once a cholesteatoma has been surgically treated, aeration of the ME can improve, and this can reduce the potential for further retraction and recurrent cholesteatoma. In the child, however, immaturity of ET function may often continue even after the cholesteatoma has been removed by surgery. This is one of the factors that could explain the continuing ME problems and

greater incidence of recurrent cholesteatoma after surgery in the paediatric population (see below). ETD may slowly improve with age but some children may experience a long period with ME pressure dysfunction. With this in mind, the follow-up of children with cholesteatoma should be for many years, as late recurrence is always a possibility.

One of the most obvious differences between children and adults is their ability to tolerate interventions and procedures. Young children may not allow their ears to be examined under the microscope, or permit aural toilet or post-operative microsuction. Many children, if treated gently and kindly, will allow treatment in the outpatient setting. However, a child does not always understand why they need what is often an uncomfortable treatment and may be unable to tolerate it.

The surgeon treating PC is often working 'against the tide' of Eustachian tube dysfunction in a patient who may not allow easy access to their ear, may not tolerate certain procedures and who may need multiple general anaesthetics. This must be borne in mind when treating PC, and when planning both the surgical approach and the need for long follow-up care. These factors, in many surgeons' opinions, make PC a more difficult condition to treat than adult disease.

Diagnosis

The symptoms and signs of cholesteatoma in an adult are usually straightforward. A history of ear discharge often with hearing loss, and on examination a tympanic membrane retraction filled with keratin debris. In children these symptoms and signs are often present but, especially in younger children or in children with congenital cholesteatoma, these symptoms may not be classic and the ear is often difficult to examine.

Younger children with CC may present with hearing loss alone, which at this age is usually suspected to be OME. Unless the drum is adequately viewed with a modern, well-illuminated otoscope or a microscope, the classic appearance of white keratin behind an intact tympanic membrane may be missed (**Figure 15.2**). If the CC is unilateral, and the other ear has normal hearing, symptoms may not become apparent until quite late, as the ear will be dry and pain-free for some years, and the diagnosis may be made only when the eardrum breaks down and the hearing is assessed and found to be poor on one side, or other complications ensue.

Many children with acquired cholesteatoma (**Figure 15.3**) will present with ear discharge and possible hearing loss. However, as discussed above, it may not be possible to perform microsuction to visualize the drum and make the diagnosis. Discharge from a chronic TM perforation after AOM is more common than cholesteatoma in children, and in both conditions florid granulation tissue and possible aural polyp formation will need treatment before the two can be distinguished. This will usually need aural toilet and antibiotic/steroid eardrops, which the child may not allow.

Making the diagnosis and visualizing the drum can therefore take time and a number of outpatient appointments. Dry mopping of the ear can be used, but with care microsuction even in younger children is possible. The use of antibiotic/steroid ear drops will reduce the inflammatory response and allow a view of the TM. In some children who will not allow access to the ear, however, an examination under general anaesthesia (EUA) is needed to thoroughly toilet the ear, remove an aural polyp if present, and see the exact pathology. In children with congenital cholesteatoma, an EUA is often needed, as it is important to perform a myringotomy to establish if the

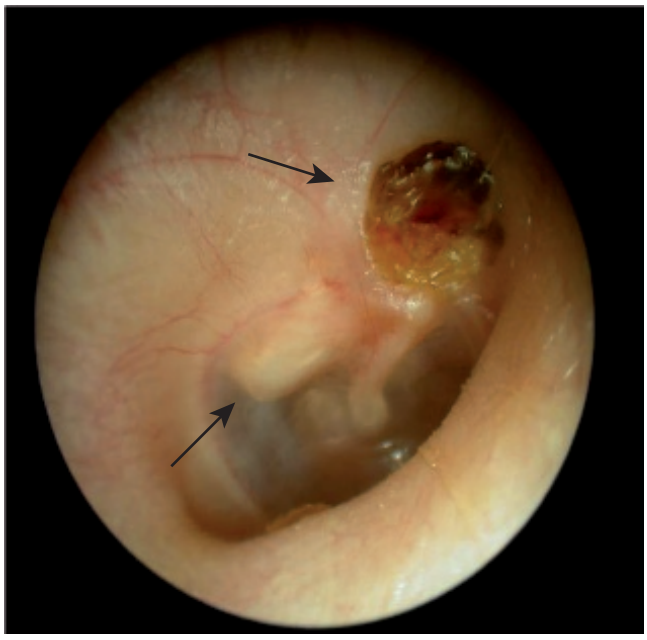

Figure 15.3 Endoscopic photo of the right ear. Thick arrow shows oxidized keratin of the cholesteatoma in the attic. The thin arrow shows the cholesteatoma sac in the posterior ME.

white appearance behind the drum is cholesteatoma, due to an unusually coloured middle ear effusion or another pathology.

MICROBIOLOGY

The bacteria cultured in paediatric COM with cholesteatoma are similar to those in adult disease. Studies show that in children with cholesteatoma *Pseudomonas aeruginosa*, *Proteus mirabilis* and *Staphylococcus aureus* are the most common isolates. Other bacteria can be found but make up a much smaller percentage of the cultures.[40] Any medical treatment used before or after surgery should therefore be targeted to treat these organisms.

IMAGING

Although children can present a difficult problem when it comes to imaging, especially in the under 8–10 years age group, knowledge of the anatomy of a child's temporal bone and the possible extent of the cholesteatoma is vital. Many children will, with the right encouragement, stay still enough for a scan to be performed, but some younger children will need a short general anaesthetic. This should be performed with great care, causing as little distress as possible, particularly as it is likely that the child will need a number of further anaesthetics in the course of their treatment for cholesteatoma, and a good experience at this stage will make the ongoing care far easier for the surgeon.

As discussed above, PC can be extensive at the time of presentation and may have spread around the bony labyrinth (**Figure 15.4**) or into the petrous apex. A computed tomography (CT) scan will give information about cholesteatoma extent but also visualization of any erosion of the bony labyrinth, facial nerve or dural plate that may be incipient or have occurred (**Figure 15.5**). CT scanning allows assessment of the degree of pneumatization of the temporal bone, the height of the middle fossa tegmen and the position of the sigmoid sinus.

Knowledge of the anatomy of the ear and mastoid and the nature of the disease spread allows the surgeon to anticipate potential intra-operative hazards and to plan the exact surgical approach that will be most appropriate to the individual, their temporal bone anatomy and their cholesteatoma.

CT scanning will give good information about the bony anatomy, with an estimation of cholesteatoma extent. This is therefore the main imaging modality. MRI scanning can

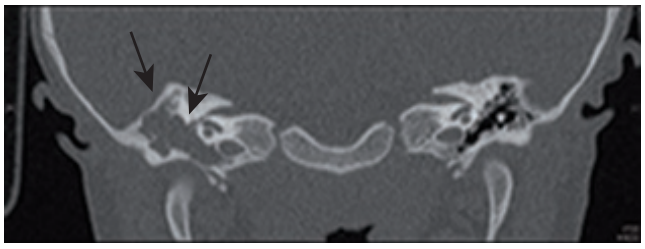

Figure 15.4 Coronal CT scan of a 5-year-old child. The arrow indicates extensive congenital cholesteatoma eroding the anterior attic and the 1st genu of the facial nerve.

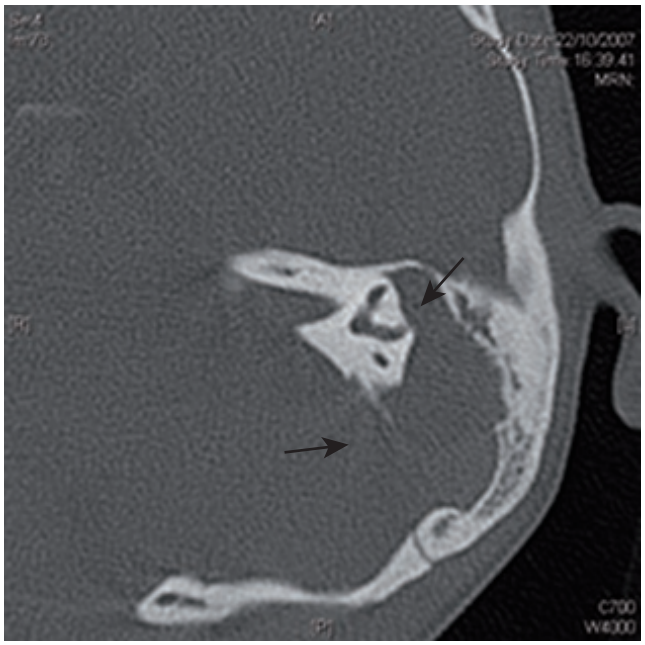

Figure 15.5 Coronal CT of a 5-year-old child. The arrow indicates extensive congenital cholesteatoma eroding the anterior attic and the 1st genu of the facial nerve.

be used but, because it takes longer and as it occurs in a confined space, it is not so well tolerated by children without general anaesthesia. It gives good soft-tissue differentiation so it can be helpful if there has been dural plate erosion to examine for intracranial cholesteatoma spread or complications, but it has a more limited role in the pre-operative workup. The use of MRI is becoming greater in the post-operative stages where it can be used for the assessment of potential residual cholesteatoma after surgery where a canal wall up procedure or a blind sac closure of the external canal has been performed. MRI can be used in the same way as it is for adult cholesteatoma[41] (see Chapter 97, Imaging of the temporal bone).

Treatment

NON-SURGICAL TREATMENT

The risk of an intracranial complication of COM has been estimated to be in the order of 1 in 10 000 every year.[42] In an elderly, medically infirm adult with cholesteatoma there is a case for conservative/medical non-surgical treatment to keep the disease under control, as it may not cause a serious complication in their lifetime. A child who develops cholesteatoma at the age of 10 and who may live to 80 will have a risk of intracranial complications in the region of 1 in 140 per year throughout their lifetime. Surgery is therefore the treatment of choice for children with cholesteatoma. There are some exceptions, including children with other significant pathology who cannot tolerate general anaesthesia such as those with major cardiac disease, but this is very uncommon.

Medical therapy with antibiotic/steroid ear drops, combined with microsuction in those children who will tolerate it, can reduce any infective element of the cholesteatoma

and help to remove accessible keratin epithelium. If there is a waiting list for surgery, medical therapy can be used to help to control the erosive process until surgery occurs.

RATIONALE OF SURGERY IN PAEDIATRIC CHOLESTEATOMA

Parents of children with cholesteatoma usually initially hope that surgery will stop the discharge and smell from the ear, and return the hearing to normal. The paediatric otologist's first job after diagnosis is to help the parents and child understand that the primary role of surgery is to:

- remove all original cholesteatoma squamous epithelial matrix
- prevent further erosion and complications
- give a dry, watertight ear
- give an ear that will be self-cleaning
- prevent the occurrence of recurrent cholesteatoma.

A secondary role of surgery is to improve hearing, but only once the primary aim of a dry, stable, disease-free ear has been achieved. It is important that parents understand that it is not possible to return truly normal hearing, and that the aim is to restore the best possible hearing in an ear that will never be 'normal'.

The parents also need to understand that paediatric cholesteatoma represents a difficult disease process in a patient who is not always cooperative with the treatment. Children do not always understand the rationale for what may be uncomfortable medical and surgical procedures. Rates of both residual and recurrent cholesteatoma are higher in children than in adults, and there is commonly the need for a number of surgeries. Parents should be counselled that the diagnosis of cholesteatoma means not a 'one-stop operation' but rather a number of procedures with a prolonged period of follow-up.

SURGICAL APPROACHES FOR PAEDIATRIC CHOLESTEATOMA

The surgical approaches for PC are no different from those for adult disease. They can broadly be divided into the traditional 'canal wall down (CWD)' surgery – modified radical mastoidectomy or for very extensive disease subtotal petrosectomy, sometimes combined with obliteration or closure of the external ear canal – and the less invasive 'canal wall up (CWU)' approaches as follows, sometimes using endoscopic techniques:

- tympanotomy/tympanoplastic surgery
- atticotomy +/– reconstruction
- canal wall up mastoidectomy/combined approach tympanoplasty.

Many of the factors that influence the surgical technique are the same in children and adults – the extent of the cholesteatoma, whether long-term follow-up can be assured, if any complications have occurred, and the anatomy of the temporal bone. The child's age, their ability to tolerate microsuction or outpatient procedures, and parental choice need also to be considered. The ideal operation for PC is tone that removes all the cholesteatoma, gives a stable self-cleaning ear and heals quickly with minimum post-operative care.

Each surgical technique has pros and cons. The decision on the exact approach must be balanced, taking into account all the factors outlined above. The surgeon who operates upon PC must have the ability to perform a wide range of procedures for cholesteatoma.

Canal wall up versus canal wall down surgery in children

A review by Osborn in 2012 of 542 procedures for paediatric cholesteatoma found 89% of cases underwent CWU surgery and 10% CWD surgery initially.[43] Over the follow-up period, ultimately 14% of the cohort received a CWD procedure. The most common reasons contributing to the decision to perform a CWD operation were disease-related: 56% showed extensive/aggressive disease with erosion of the canal wall (**Figure 15.6**) or the need to remove attic bone. Anatomical reasons accounted for 43% (poor mastoid pneumatization, low tegmen, anterior sigmoid).

CANAL WALL UP SURGERY

Canal wall up (CWU) surgery endeavours to remove all the cholesteatoma but to retain the canal wall and a middle ear closed at the level of the original tympanic membrane. This can be achieved by operating via the canal in the case of localized ME choleasteatoma, with removal of some of the medial canal with an atticotomy or bony marginectomy and then reconstructing the defect and repairing the drum, or by a combined transmastoid and transcanal approach (often called a combined approach tympanoplasty (CAT) or a canal wall up mastoidectomy with tympanoplasty). The philosophy of these approaches is to leave an ear with a normal external canal and a stable reconstructed tympanic membrane.

The benefits and downsides of these CWU approaches in the child, if successful, are given in **Box 15.1**.

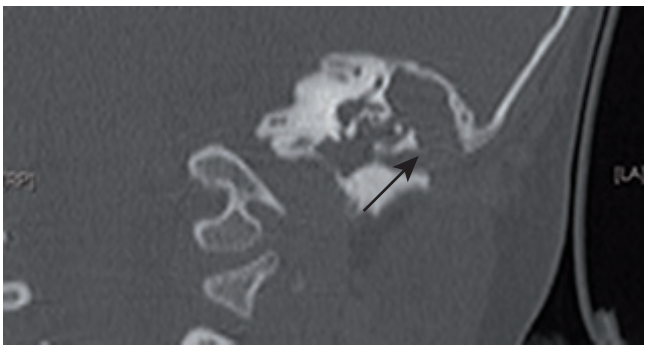

Figure 15.6 Coronal CT scan in an 8-year-old child. Extensive cholesteatoma filling the left mastoid and middle ear, with erosion of the external ear canal (arrow).

BOX 15.1 Benefits and downsides of CWU surgery in children

Benefits	Downsides
Normal ear canal and reconstructed tympanic membrane which does not need to be kept dry	The possible need for a 'second look' operation
Rapid healing as only a small area needs re-epithelialization	The possibility of recurrent cholesteatoma from the reconstructed tympanic membrane
Ear packing usually needed only once after surgery and removed in the outpatient clinic	Technically more demanding surgery
Able to use a normal hearing aid if hearing outcome not satisfactory	
Should not need ongoing microsuction to clean ear	

CANAL WALL DOWN SURGERY

In canal wall down (CWD) mastoidectomy or modified radical mastoidectomy the ear canal wall and the attic scutum are removed to give access to the middle ear, mastoid and attic and to clear the keratin epithelium. CWD surgery gives better intra-operative access to all areas of the ear. The surgical cavity formed is grafted to hopefully allow the migratory epithelium of the tympanic membrane remnant to grow around the cavity. Ideally this creates a bony cavity covered by a dry migratory squamous lining, with the remaining ME and Eustachian tube sealed off from the outside world. However, not every ear heals as well as can be hoped, and a proportion of mastoid cavities may continue to discharge or be wet, for a number of reasons. The 'wet ear' rate may be as low as 5%, but it can be far higher. In the child a wet mastoid cavity that is hard to access and clean presents a very difficult management problem. Males and Gray called this a 'mastoid misery', and many of these discharging cavities will need revision surgery.[44]

The benefits and downsides of the CWD approach in the child are given in Box 15.2.

RESIDUAL AND RECURRENT CHOLESTEATOMA IN CHILDREN

Childhood cholesteatoma has much greater rates of residual and recurrent disease than that seen in adults.[45] **Residual cholesteatoma** is the keratin epithelium that the surgeon failed to remove at the initial operation, so that it grows back (Figure 15.7). **Recurrent cholesteatoma** occurs when squamous epithelium begins to grow again into the middle ear cleft at a new site, either with invagination of the reconstructed tympanic membrane or through a weakness in the reconstruction (Figure 15.8). The term **recidivism** is sometimes used, combining residual and recurrent cholesteatoma. This can confuse as residual cholesteatoma occurs due to inadequate clearance of the initial disease and is therefore purely related to surgical

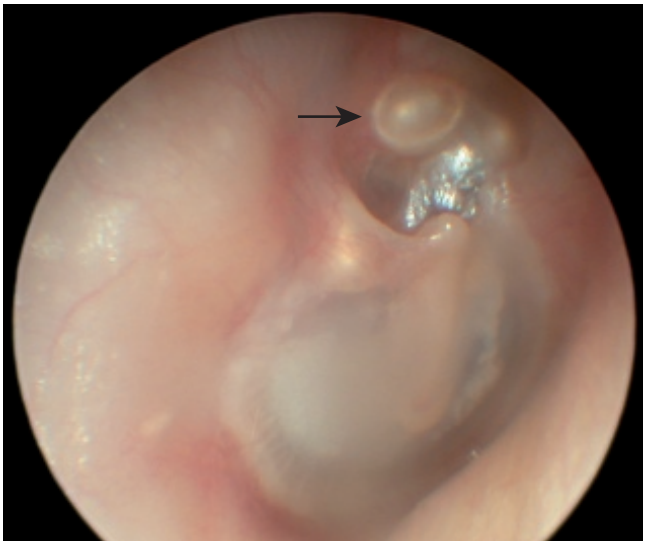

Figure 15.7 Endoscopic photo of a child's left ear, one year after CWU surgery for attic cholesteatoma. Arrow indicates residual cholesteatoma pearls under grafted attic area.

BOX 15.2 Benefits and downsides of CWD surgery in children

Benefits	Downsides
One major operation	A larger mastoid cavity
A cavity that can easily be inspected	If the cavity does not heal well, a discharging ear
Reduction of volume of middle ear and mastoid, so the Eustachian tube has less to ventilate, hopefully leading to a reduction in recurrent cholesteatoma	In an uncooperative child, often several general anaesthetics
	Often the cavity needs to be kept dry, as cold water can stimulate a caloric effect, so swimming may be restricted
	Sometimes difficult to use a hearing aid in a cavity
	After ME inflammation (common in the child) a cavity can be become unstable and discharge

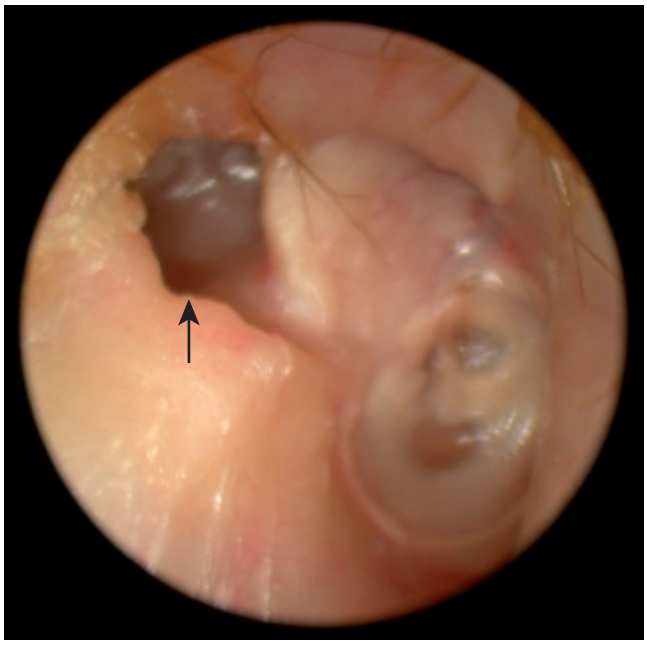

Figure 15.8 Endoscopic photo of right ear some years after CWU surgery for attic cholesteatoma. The attic has been reconstructed with cartilage but there is recurrent retraction cholesteatoma posterior to this (arrow).

technique, whereas recurrent cholesteatoma may occur due to inadequate surgical reconstruction but is caused by the underlying process that drives cholesteatoma formation (such as Eustachian tube dysfunction), which may continue in the child even after surgery.

It would seem logical that, with the challenges of more difficult surgical access, CWU surgery would have a greater incidence of residual disease than CWD. There may be a trend towards this, but in CWD surgery there are still significant rates of residual cholesteatoma in children. These high residual rates are probably related to the greater extent of the initial disease, often in a well-pneumatized temporal bone.

Residual cholesteatoma rates in the literature for children after surgery range from 6% to 43% in CWU surgery[27,43,46–49] and from 6% to 38 % in CWD surgery.[43,50–52] It seems that rates of residual cholesteatoma can be reduced with the use of modern techniques and the increasing use of the laser and otoendoscope[53] (see Chapter 87, Otoendoscopy).

Recurrent cholesteatoma in CWU would be expected to be more common than in CWD, where there is a reconstructed tympanic membrane and larger ME cleft for re-retraction to occur. However, recurrent retraction and cholesteatoma formation does occur with CWD surgery in children, with epithelial pockets insinuating themselves into the temporal bone. This process can occur slowly over many years after both CWU and CWD operations and is probably a reflection of the ongoing Eustachian tube dysfunction in the child. A long period of post-operative follow-up is needed for any child who has had surgery for cholesteatoma.

In CWU surgery, cholesteatoma recurrence in children at 5 years post-operatively has been found by some reviews to be 17–25%.[49,52,54] More recently, techniques of obliteration of the mastoid in CWU surgery have shown lower rates of recurrence (3%),[46] and it is possible that reducing the volume of the middle ear and mastoid that the Eustachian tube has to ventilate may help reduce the recurrence rate. Cartilage reinforcement of the reconstructed drum may also help prevent recurrent cholesteatoma (**Figures 15.9** and **15.10**).

In CWD surgery recurrence rates of 7–25% are described at 5 years[43,51,54,55] but some retraction pockets in a mastoid cavity may form recurrent cholesteatoma up to 13 years after the initial surgery.[51] Other studies have found ongoing recidivism at up to 25 years post-operatively.[56]

Paediatric cholesteatoma represents a difficult disease process with higher rates of post-surgery residual and recurrent disease when compared to adults. This is in a patient who may not tolerate outpatient intervention so well and may not keep their ear dry as requested. There are a number of surgical options but, whichever technique

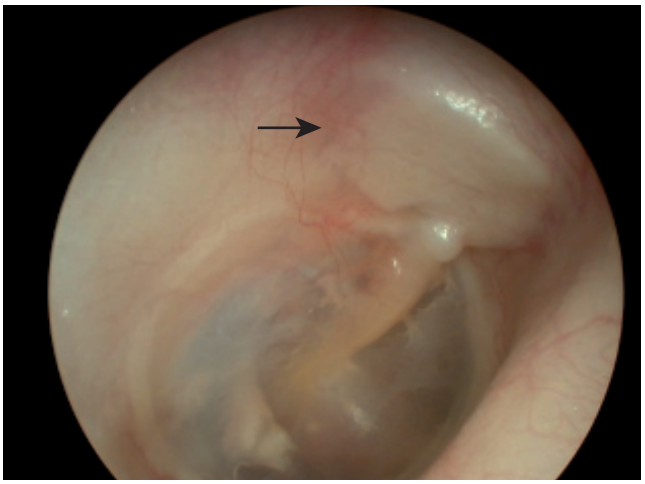

Figure 15.9 Endoscopic photo of a child's right ear. Arrow indicates cartilage reconstruction of the attic defect after CWU surgery for attic cholesteatoma.

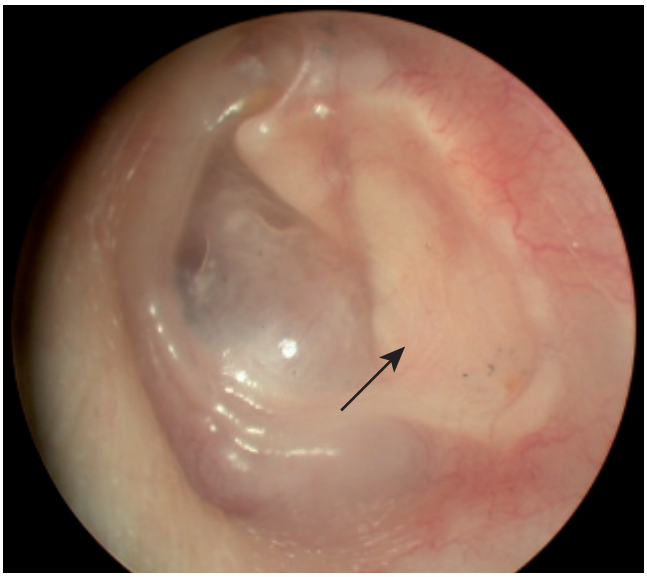

Figure 15.10 Endoscopic photo of the left ear. Posterior tympanic membrane reconstruction with cartilage (arrow) after CWU surgery for posterior pars tensa cholesteatoma.

is chosen, the surgeon will need to use meticulous care to ensure that all the existing cholesteatoma is removed.

In paediatric cholesteatoma over the last 10 years many surgeons have moved away from CWD surgery because of the problems associated with managing a mastoid cavity in children – the potential for 'mastoid misery'.

COM WITH CHOLESTEATOMA IN CHILDREN WITH OTHER SYNDROMES

Children with Down syndrome have an increased incidence of cholesteatoma possibly related to poor Eustachian tube function and midface hypoplasia.[57] Diagnosis of cholesteatoma in this group can be difficult as they often will have small external ear canals and may have learning difficulties. The anatomy of the ear is also challenging with small external canals, poor mastoid pneumatization and often a low mastoid tegmen. Access to the middle ear via the mastoid for a CWU procedure can be very limited and CWD surgery may need to be considered.[58] The facial nerve in children with Down syndrome can run in a more superficial or abnormal course. Care must be taken with mastoid surgery in these children, with the path of the intratemporal bone facial nerve identified on the imaging pre-operatively and the facial nerve monitor used to aid its identification intra-operatively. Careful thought is needed when choosing the operative approach and discussing outcomes with the parents.

Children with craniofacial syndromes, and also di George syndrome (22q11.2 deletion), similarly have a higher risk of cholesteatoma, probably again due to poor palatal and Eustachian tube function. If the child has microtia or a very narrowed external auditory canal with or without these syndromes, it can be difficult to assess the state of the tympanic membrane. An increased suspicion of the presence of COM with or without cholesteatoma should be borne in mind in these cases.

BEST CLINICAL PRACTICE

- ✓ Children with ear disease often need a number of procedures so gentle care is important to prevent a child becoming afraid and adverse to treatment.
- ✓ Imaging of the temporal bone in paediatric cholesteatoma is valuable to gauge disease spread, anatomy and to plan the surgical approach.
- ✓ Cholesteatoma surgery in children requires the surgeon to have the ability to perform a variety of otological approaches.
- ✓ Tympanomastoid surgery can be especially challenging in syndromic children.
- ✓ Residual and recurrent cholesteatoma is greater than in adults and long-term follow up is needed in children.

KEY POINTS

- Paediatric cholesteatoma is thought to be more aggressive than its adult counterpart.
- Children may not tolerate outpatient treatment or microsuction of the ears.
- Paediatric cholesteatoma is a surgical disease. Conservative treatment is very rarely appropriate.
- Canal wall up (CWU) techniques are increasingly preferred in children.
- Endoscopy and use of the laser may reduce the risk of residual cholesteatoma post surgery.

CHAPTER 16

MICROTIA AND EXTERNAL EAR ABNORMALITIES

Iain Bruce and Jaya Nichani

SEARCH STRATEGY

Data in this chapter may be updated by a PubMed search using the keywords: microtia, congenital canal atresia, preauricular sinus, preauricular appendage and unilateral hearing loss.

INTRODUCTION

Abnormal development of the external ear can affect hearing, communication, education, cosmesis and increase the risk of recurrent infections. Our understanding of the consequences of unilateral hearing loss (UHL) upon childhood development continues to expand. While many children with unilateral hearing loss develop normally, some children experience negative effects upon development. The management of the cosmetic consequences of microtia should not occur in isolation, but in combination with the rehabilitation of hearing loss resulting from congenital canal atresia (CCA). Failure to manage cosmesis and hearing loss in combination can result in delayed intervention for hearing loss and/or the compromising of reconstructive options and ultimate outcome.

ANATOMY OF THE EXTERNAL EAR

The pinna, external auditory canal and outer epithelial layer of the tympanic membrane constitute the external ear.

Pinna

The **pinnae** are paired structures with a cartilaginous framework. The inferior part of the pinna (**lobule**) does not have a cartilaginous framework and is only supported by a fibrofatty matrix. The **helix** is the outermost cartilaginous curvature of the pinna. The curve of the **antihelix** runs inside and parallel to the curve of the helix. The antihelix divides superiorly to forms two crura: the **superior crus** and the **inferior crus**. The depression between the two crura is called the **triangular fossa**. Anterior to the antihelix is the concave depression called the **concha**. The conchal bowl is subdivided into the **cymba concha** superiorly and the **concha cavum** inferiorly. The elevation of cartilage anterior to the entrance of the external ear canal is called the **tragus**. The **antitragus** is the inferior-most prominence of the antihelix curvature opposite the tragus, and the gap between the tragus and the antitragus is called the **intertragal notch**. The cartilage of the pinna is continuous with the cartilaginous ear canal, thereby fixing it to the temporal bone along with muscles and ligaments (anterior, posterior and superior ligaments). The intrinsic muscles of the pinna are poorly developed; the extrinsic muscles (anterior, posterior and superior) may be well developed in some individuals.

External auditory canal

The **external auditory canal** (EAC) extends from the concha cavum to the tympanic membrane. It comprises a cartilaginous framework in its outer one-third and a bony canal in the medial two-thirds. The skin and the subcutaneous tissue lining the cartilaginous ear canal contain hair

follicles and glandular structures, whereas the bony canal is covered by a tightly adherent layer of epidermis. The external ear canal is 3–4 cm in length, with the anterior part of the canal being longer and more curved than the posterior canal.

Size and position of the external ear

At birth the anatomical landmarks of the pinna are fully formed. Subsequently, it grows to reach adult size by 8–10 years of age, measuring approximately 60 mm in length. Generally, the superior margin of the pinna lies in line with the eyebrow, and the lower limit of the lobule is in line with the base of the nasal septal columella.[1] It is inclined approximately 15–20° posteriorly and protrudes 15–20 mm from the scalp.

EMBRYOLOGY OF THE EAR

External ear

At 5 weeks of gestation, five paired structures (1, 2, 3, 4 and 6 **pharyngeal arches**) are visible externally, lying close to the developing neural crest. Each pharyngeal arch has an internal endodermal pouch, an external ectodermal cleft and a mesenchymal core which gives rise to an associated named blood vessel, nerve, muscle and cartilage. The external ear develops from the first two pharyngeal arches.[2]

Six nodular swellings called **hillocks of His** develop from the first and second arches, three on either side of the first pharyngeal cleft. Growth, differentiation and fusion of these hillocks result in formation of the pinna. The tragus, helix and cymba concha develop from the hillocks arising from the first arch, while the concha cavum, antihelix and antitragus arise from the hillocks of the second arch. The developing pinna is initially located in the neck and, by 20 weeks of gestation, it ascends to reach its normal location.[3]

The EAC develops from deepening of the first pharyngeal cleft. The first pharyngeal pouch deepens to contact the first cleft. As the embryonic connective tissue proliferates between the first pouch and the first cleft, the contact between the two developing structures is lost and the **meatal plate** develops. The meatal plate starts to canalize between 21 and 28 weeks, forming the inner two-thirds of the EAC. The innermost portion of the meatal plate contributes to the outer layer of the tympanic membrane.

Middle ear

The first and second pharyngeal arches and the first pharyngeal pouch contribute to the development of the middle ear. The middle ear and the inner layer of the tympanic membrane develop from the first pharyngeal pouch. The ossicles develop from the first two pharyngeal arches (malleus and incus from the first arch and the stapes from the second arch).

Inner ear

At week 4 of gestation surface ectodermal cells of the neural plate differentiate into sensory cells and form the **otic placode**. The developing otic placode lies close to the embryonic hindbrain, which contributes to the development of the vestibulo-cochleo-facial ganglion complex. The otic placode invaginates and forms the **otic vesicle**, which gives rise to the membranous labyrinth. The bony labyrinth forms from the periotic mesoderm.

Facial nerve

The facial nerve originates from neural crest cells. The neural crest cells arising from the hindbrain are closely related to the developing pharyngeal arches. The neurons of the first three branchial arches are derived from the neural crest cells (rhombomeres) and form cranial nerves V, VII and IX. The development of these cranial nerve nuclei occurs around the fourth week of embryogenesis and is complete by 16 weeks. Ossification of the Fallopian canal continues into the late foetal period. As the development of the facial nerve and the second arch are closely linked, abnormalities of the facial nerve are often associated with a malformed stapes.

DEVELOPMENTAL ANOMALIES OF THE EXTERNAL EAR

Preauricular sinus

The opening of a preauricular sinus is found in front of the helix, leading into a sinus tract lined with squamous epithelium (Figure 16.1). The tract lies in the subcutaneous tissues lateral to the temporalis fascia superiorly and parotid fascia inferiorly, and with a tortuous and branching course. The terminal portion of the tract is adherent to

Figure 16.1 Left preauricular sinus.

the cartilage of the helix. Preauricular sinuses are postulated to develop from defective or incomplete fusion of the hillocks of His during auricular embryogenesis. An alternative theory suggests that isolated or localized folding of ectoderm during auricular embryogenesis is the cause of preauricular sinus formation.[4]

Preauricular sinuses occur sporadically or may be inherited. Sporadic abnormalities are generally unilateral and bilateral preauricular sinuses are more likely inherited. Preauricular sinuses may be associated with several syndromes, most notably branchio-oto-renal syndrome. It has been suggested that preauricular sinuses may be linked with anomalies in the region of chromosome 8q11.1-q13.3.[5] Renal anomalies are commonly associated with external ear anomalies, particularly preauricular sinuses, with these patients often investigated using renal ultrasound to detect concurrent renal abnormalities. To aid selection of patients for renal ultrasonography, the following criteria have been suggested:[6]

- maternal history of gestational diabetes
- family history of ear anomalies or hearing loss
- associated craniofacial abnormalities
- associated cardiac abnormalities
- associated gastrointestinal abnormalities
- associated limb abnormalities.

The authors suggest that a preauricular sinus, or any other external ear abnormality, associated with any of the above findings is an indication for a renal ultrasound.

INDICATIONS FOR SURGERY

The decision to operate is usually influenced by the frequency and severity of infective episodes, chronicity of sinus discharge and the development of unsightly overlying skin inflammation (**Figure 16.2**). Incision and drainage should be avoided in acute infections due to the risk of sinus disruption and seeding, and less likely facial nerve injury. Acute infections are best treated with intravenous antibiotics and in severe cases needle aspiration with microbiology culture of the aspirate.[7]

SURGICAL TECHNIQUE

Several techniques have been suggested for excising preauricular sinuses including curettage, microdissection and wide local excision. When selecting a surgical technique, the fact that the sinus may branch extensively and be adherent to the pinna cartilage must be taken into consideration. Curettage is no longer routinely performed due to high recurrence rates and unsightly scarring. Microdissection techniques rely upon identification of the extent of the sinus and its branches, with lacrimal probes and methylene blue being used to delineate the sinus. The 'supra-auricular' approach involves identification of the plane of the temporalis fascia and dissection of the soft tissue between this plane and the helix of the pinna, remaining posterior to the parotid fascia, and without a formal attempt to identify the extent of the sinus and its branches.

Figure 16.2 Left preauricular sinus with inflammation of the overlying skin.

The resultant wide local excision is considered to give the lowest recurrence rate. Care must be taken to avoid facial nerve injury in revision cases and when skin and soft-tissue inflammation is extensive.[7]

Preauricular appendages

Preauricular appendages result from abnormalities of embryogenesis of the external ear[8] and may be unilateral or bilateral, solitary or multiple. These appendages have a fibrofatty core and often contain a cartilaginous component. They are usually found along a line drawn from the tragus to the angle of the mandible, reflecting origin from the first branchial arch. An increased risk of associated permanent hearing loss has been suggested in infants with preauricular appendages (**Figure 16.3**).[9]

INDICATIONS FOR SURGERY

Operating upon preauricular appendages is undertaken to improve cosmesis and facial symmetry. Surgery is usually undertaken after 1 year of age. Preauricular appendages associated with microtia may be operated upon to improve facial symmetry while waiting for the child to reach an age when ear reconstruction is considered.

SURGICAL TECHNIQUE

Appendages may contain a deeply extending cartilaginous core that may be more extensive than apparent from examination of the external component. Care must therefore be taken when resecting the deep components of

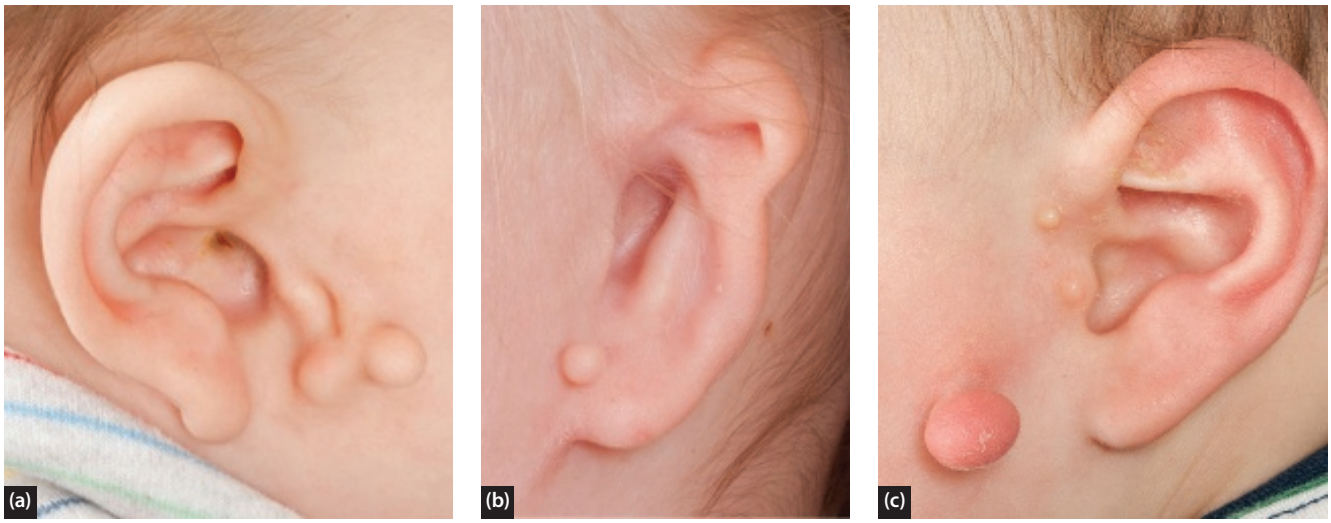

Figure 16.3 Preauricular appendages. **(a)** Associated with a mildly dysplastic right pinna; **(b)** associated with microtia of the left pinna; **(c)** associated with an otherwise normally developed pinna.

the appendage, due to the potential for inadvertent facial nerve injury. Often complete excision of the skin and soft-tissue components is undertaken with partial resection of the superficial part of the cartilaginous core.

MICROTIA

Microtia is a congenital abnormality in which the pinna (auricle) is malformed (see Figure 16.3b). This malformation, or underdevelopment, may be associated with congenital canal atresia or canal stenosis. The incidence of microtia has been reported to be 1 in 10000 and environmental and genetic factors are suggested aetiological factors.[10] CCA often accompanies significant microtia. Results following surgical correction of CCA (canaloplasty) are often disappointing, with a significant risk of chronic discharge and the persisting requirement for amplification. Children with canal stenosis, and those who have undergone canaloplasty, are at risk of developing a canal cholesteatoma and require regular monitoring and interval radiological surveillance.

Grading of microtia and CCA

Several attempts have been made to grade microtia and CCA in a clinically relevant manner, based on clinical, surgical and radiological characteristics (Table 16.1).[11–14] High-quality digital images of the external ear and face often prove more useful as a record of pre-operative appearance and for surgical planning. The pinna malformation may range from mild dysplasia (Figure 16.4) to complete lack of development of the external ear (anotia).

Clinical assessment of children with microtia

A multidisciplinary team is best placed to assess a child with microtia and any associated EAC atresia or stenosis. Attention to the following aspects of clinical and audiological assessment is required.

CLINICAL ASSESSMENT

This involves assessing the general health of the child, with respect to any comorbidity that may affect their management. Some children will also benefit from a psychological assessment, focused on coping with any anxiety associated with their condition and its management. Key points to be considered during assessment are:

- unilateral or bilateral microtia
- size of the microtic ear and its location
- development of the contralateral pinna in unilateral microtia
- hairline
- site and size of a remnant lobule
- presence or absence of normal skin separating the remnants of the microtic ear – this may suggest a superficial course of the facial nerve and caution is exercised during reconstruction to avoid damage to the superficially placed facial nerve
- presence of a stenotic ear canal
- growth and development of the mastoid bone
- space between the temporomandibular joint (TMJ) and the mastoid tip
- presence or absence of facial asymmetry (e.g. hemifacial microsomia in Goldenhar syndrome) (Figure 16.5)
- facial nerve function.

AUDIOLOGICAL ASSESSMENT

Children with microtia and canal stenosis/atresia will usually have a conductive hearing loss (CHL). A small proportion of these children may also have an underlying sensorineural hearing loss (SNHL). It is important to establish ear-specific bone conduction thresholds in early

TABLE 16.1 Examples of grading systems for microtia and congenital canal atresia

	Grading system	Description			
Microtia	Marx[11] *Based on clinical appearance*	**Grade 1** Smaller pinna, but all features of a normal pinna are recognizable	**Grade 2** Some features of a normal pinna are recognizable	**Grade 3** Rudiment of soft tissue and cartilage ('peanut')	**Grade 4** Absent pinna and ear canal
	Weerda[12] *Based on surgical management*	**1st degree dysplasia** Most structures of a normal pinna are recognizable (minor deformities)	**2nd degree dysplasia** Some structures of a normal auricle are recognizable	**3rd degree dysplasia** None of the structures of a normal pinna are recognizable	**Anotia** Absence of external ear
		Surgical definition: Reconstruction does not require the use of additional skin or cartilage	*Surgical definition:* Partial reconstruction requires the use of some additional skin and cartilage	*Surgical definition:* Total reconstruction requires the use of skin and large amounts of cartilage	
CCA	Weerda[13] *Based on clinical appearance*	**Type A** Marked narrowing of EAC with an intact skin layer	**Type B** Partial patency of the lateral EAC with an atretic medial meatal plate		**Type C** Complete atresia of the EAC
	Jahrsdoerfer[14] *Based on radiological appearance*	**Parameter** Stapes present Oval window open Middle ear space Facial nerve normal Malleus/incus complex present Mastoid well-pneumatized Incus/stapes connection Round window normal Appearance of external ear **Rating** 10 9 8 7 6 ≤5			**Points allocated** 2 1 1 1 1 1 1 1 1 **Surgical candidate** Excellent Very good Good Fair Marginal Poor	

infancy to enable appropriate management decisions. Management of bilateral CHL in children with bilateral CCA is of fundamental importance to normal speech and language development. In children with unilateral hearing loss, there is emerging evidence to support early intervention, as discussed below.

Management of significant microtia

The multidisciplinary team delivering care should be able to offer both hearing rehabilitation and all types of pinna reconstruction. Most commonly, children with microtia have three options regarding cosmesis: no intervention, autologous ear reconstruction using cartilage, and bone-anchored auricular prosthesis (BAAP). A proportion of children and young people with significant dysplasia will prefer to keep their 'special ear' and refuse intervention.

AUTOLOGOUS EAR RECONSTRUCTION

This requires two to four surgical procedures dependent upon the technique used (see Vol 3, Chapter 96, Partial and total ear reconstruction). The predominant principles of this procedure include construction of a cartilaginous framework, soft-tissue cover and projection of the reconstructed pinna. Autologous rib cartilage is harvested and used to carve the new cartilage framework. Timing of

Figure 16.4 Dysplastic left pinna in a girl with CHARGE syndrome.

Figure 16.5 Unilateral right microtia in a boy with Goldenhar syndrome. He has right hemifacial microsomia and a left epibulbar dermoid.

surgery will depend on availability of requisite amount of cartilage (8–10 years), and the child's ability to cooperate with the demands of surgery.

The risk of resorption and extrusion of the framework is lower in autologous cartilaginous frameworks as compared to frameworks made from artificial materials.

BONE-ANCHORED AURICULAR PROSTHESIS

A specialist prosthetist is critical in the surgical planning, production of an appropriate prosthesis, and aftercare of older children and young people fitted with bone-anchored auricular prostheses (BAAPs). A BAAP necessitates removal of the vestigial ear (including the lobule), therefore precluding subsequent autologous ear reconstruction if the recipient was dissatisfied with the BAAP. The surgeon and prosthetist must agree the position of the two osseointegrating fixtures. The choice of single- or two-stage surgery is made in the same way as for BAHA insertion. Following osseointegration, a gold retention bar is attached to the abutments, with the prosthetic ear clipping onto this bar. Reasons for opting for a BAAP include patient preference, failed autologous ear reconstruction and significant comorbidities precluding autologous ear reconstruction. The cosmetic outcome of an auricular prosthesis is closely linked to the experience of the prosthetist, with an experienced prosthetist able to add fine contouring and closely match skin colour. However, despite this, some patients prefer a reconstructed pinna that is made from their own tissues. Recurrent soft-tissue inflammation and traumatic fixture loss may complicate the use of percutaneous abutments, as encountered in percutaneous BAHA.

UNILATERAL HEARING LOSS IN CONGENITAL CANAL ATRESIA

Consequences of unilateral hearing loss in children

Traditionally, the presumption has been that UHL would not adversely affect speech and language and academic attainment, if the hearing thresholds in the contralateral ear were within the normal range. However, this assumption is now being challenged, with increasing evidence suggesting that significant numbers of these children could perform better with appropriate management and support.

The work of Lieu and colleagues has described and demonstrated the impact of UHL during childhood, with resultant underperformance in speech, language and cognition in children and young people. Regarding educational performance, a review of UHL (mild to profound severity) in children found a rate of 22–35% for repeating at least one grade and a rate of 12–41% for receiving educational assistance.[15] Lieu also demonstrated in a prospective 3-year longitudinal cohort study of 46 children aged

Figure 16.6 Child with Treacher Collins syndrome and microtia with CCA. The child is wearing a BAHA on a softband and has a tracheostomy *in situ*.

6–12 years with permanent UHL that parents and teachers reported persistent behavioural problems and academic weaknesses or areas of concern in approximately 25% of the cohort.[16] A further case control study of 20 young people (12–17 years) with UHL demonstrated that UHL was associated with a negative effect on standardized language scores and IQ persisting into adolescence. Sibling controls helped to ameliorate any bias resulting from socioeconomic, environmental and genetic factors. The authors also describe children with UHL having difficulty with listening in background noise and sound localization.[17]

Accepting the evidence for the potential negative impact of UHL upon development, the question remains as to the timing of the intervention: before or after the onset of clinically apparent underperformance. Gordon et al. have postulated the existence of aural preference syndrome, in which single-sided deafness in early childhood reorganizes the developing auditory pathways in favour of the hearing ear, and to the detriment of the cortical representation of the deaf ear. They recommend early intervention to secure functioning in the impaired auditory pathway and for restoring (or enabling) binaural hearing.[18] Early intervention would also be supported by the Fischer and Lieu study in which the cohort of young people had not closed the developmental gap with their siblings by adolescence.[17] In broad agreement with the concept of early intervention, the recently developed UK Care Standards for the Management of Patients with Microtia and Atresia[19] advocate the fitting of a bone conduction hearing device (BCHD, e.g. BAHA softband) in infants with microtia and CCA (**Figure 16.6**).

Managing hearing loss in congenital canal atresia

Central to the management of UHL in microtia with CCA is the expectation that in approximately 90% of cases the underlying cochlea function is maintained.[20] Secondly, transcranial attenuation is greater in early infancy, due to the stepwise fusion of the cranial bones during childhood. Therefore, infants and young children will have less transcranial transmission of signal from a BCHD than older children and adults. Also, it is possible to obtain accurate ear-specific bone conduction thresholds in early infancy, despite an inability to mask in a conventional manner in the absence of an external auditory canal.

SYNDROMES ASSOCIATED WITH EXTERNAL EAR ABNORMALITIES

Certain syndromes can be associated with abnormalities of the external ear (**Table 16.2**).[7] Understanding of the manifestations of these conditions is necessary as some may also be associated with other head and neck abnormalities, including abnormalities of the middle and inner ears, and craniofacial abnormalities. Involvement of other body systems (e.g. congenital heart disease (CHD) in a child with Down syndrome) may also be important when planning any surgical intervention under general anaesthesia. Knowledge of cognitive impairment is of critical importance when assessing the likely impact of hearing loss upon development and educational performance.

TABLE 16.2 Syndromes commonly associated with microtia and external ear abnormalities (adapted from Bruce[7])

Syndrome	Description	Chromosomal abnormality	External ear abnormality	Middle and inner ear abnormality
Treacher Collins (Figure 16.6)	Results from abnormal development of structures derived from the first and second pharyngeal complexes	*TCOF1* gene mutations	Bilateral microtia CCA	Ossicular abnormalities
Goldenhar (Figure 16.5)	Heterogeneous disorder associated with hemifacial microsomia, epibulbar dermoid, CHD and vertebral abnormalities	Cause unclear; several chromosomal abnormalities have been described	Unilateral microtia Preauricular appendages	Ossicular abnormalities Abnormal facial nerve anatomy
CHARGE (Figure 16.4)	**C**oloboma, **H**eart defects, **A**tresia choanae, **R**etarded growth and development, **G**enital abnormalities, **E**ar abnormalities	*CHD7* gene mutations	Dysplastic pinnae	Various middle and inner ear abnormalities Facial nerve palsy
Branchio-oto-renal	Branchial cleft abnormalities, ear abnormalities and renal malformations	*EYA1*, *SIX1* and *SIX5* gene mutations	Preauricular sinuses or tags	Ossicular abnormalities WVA Malformed cochlea and vestibular apparatus
Down	Multisystem involvement	Trisomy 21	Small, low-set pinnae Narrow EAC	Hypoplastic mastoid IAC stenosis Vestibular malformations

CCA, congenital canal atresia; CHD, congenital heart disease; WVA, wide vestibular aqueduct; EAC, external auditory canal.

KEY POINTS

- When managing a child with microtia and congenital canal atresia (CCA), consideration should be given to both cosmesis and hearing rehabilitation.
- Cosmesis and hearing should be managed together by a multidisciplinary team.
- In CCA cochlear function is usually normal.
- All children with CCA should undergo regular assessment of hearing, speech and language and educational performance.
- Some children with CAA benefit from a bone conduction hearing device (BCHD).
- Early fitting of BCHD in infants and young children with CCA may be advantageous.
- Bone conduction implants (BCI) should only be inserted in close cooperation with an ear reconstruction service, to prevent inadvertent negative impact upon reconstructive options.

ACKNOWLEDGEMENT

The authors would like to acknowledge Leslie Molina Ramirez, University of Manchester, for review of the section 'Syndromes associated with external ear abnormalities'.

CHAPTER 17

DISORDERS OF SPEECH AND LANGUAGE

Suzanne Harrigan and Andrew Marshall

SEARCH STRATEGY

Data in this chapter may be updated by a PubMed search using the keywords: communication, language, speech, developmental milestones, speech and language therapy.

INTRODUCTION

We live in a world where communication is vital. Modern technologies, including the internet and mobile devices, mean that we can communicate with many more people and across greater distances than at any time in history. In the developed world, jobs that require interaction with others are more prevalent than they were in the last century; the office for national statistics in the UK reports that approximately 71% of men and 92% of women are now employed within service industries, where the skills of interpersonal communication are essential. So, in order to succeed and thrive, both in education and the workplace, the children of the 21st century require a level of spoken language and, in turn, literacy that can be achieved only through exposure to a rich and vibrant language learning environment. For those children who, for whatever reason, fail to develop adequate speech, language and communication skills, the future can be bleak, with a significant percentage of them running the risk of poor attainment levels at school and potentially slipping into antisocial behaviour. Bryan identified high levels of speech, language and communication difficulties within the young offender population.[1] Ironically, however, there appears to be a lack of awareness about the importance of speech and language development in the general population. In a report from the Communication Trust[2] as many as 50% of children were identified as having problems with speech and language on school entry. It is therefore essential that all professionals who come into contact with children are familiar with the developmental milestones for speech and language acquisition in order to intervene both medically and from a multidisciplinary perspective.

This chapter aims to provide the reader with a brief summary of childhood speech and language acquisition, with a particular focus on the first 5 years of life, when the foundations of language for learning and literacy are established. Some of the obstacles that may delay or hinder the developmental process will also be discussed and the 'red flags' that may indicate the presence of speech and language difficulties will be highlighted to ensure that ENT professionals are aware of these warning signs and act in a timely manner, rather than falling into the 'wait and see' trap that often occurs.

A WORD ABOUT TERMINOLOGY

Before looking at the developmental milestones, it is worth considering the terminology used to describe communication, language and speech development.

Pragmatics: using and understanding language in different situations
Verbal skills: understanding and using spoken language
Non-verbal skills: communicating using signs, gestures and body language

Expressive skills: getting a message across, verbally or non-verbally

Comprehension or receptive skills: understanding of language

Voice skills: volume, quality and pitch, which can be used to convey changes in meaning through intonation

Speech: pronouncing sounds and words. Speech and language therapists assess children's speech production in terms of the child's articulation – the physical capability to produce sounds, or phonology, i.e. the child's ability to use a range of sounds contrastively within the rules of the spoken language used.

MILESTONES FOR SPEECH, LANGUAGE AND COMMUNICATION DEVELOPMENT

This section will describe the stages in the development of speech, language and communication over the first 5 years of a child's life (summarized in Table 17.1). However, there is considerable evidence that the process of learning about voices and communication begins before birth, as the mother's speech patterns, particularly prosody (patterns of stress and intonation), are readily available to the baby in the womb. This means that hearing babies arrive in the world with a range of auditory experiences.[3, 4] Babies with hearing losses have therefore already experienced a period of auditory deprivation, despite the earlier identification of hearing problems in babies and management of childhood hearing loss.

Figure 17.1 illustrates the stages in the normal development of speech and communication in the first 5 months.

Birth to 3 months

Babies are born with a desire to communicate and are skilled at getting others to communicate with them. Newborn babies love looking at the human face and will try to copy facial movements. They have different cries for different physical states, so parents quickly begin to differentiate between a hungry cry and a cry of pain. As babies approach the age of 3 months, they are already becoming social beings, with the development of the social smile and laughter. Hearing babies startle to loud sounds and are particularly interested in and calmed by the sound of friendly voices, particularly their parents'. This emphasizes the need for babies with hearing losses to be provided with appropriate amplification as soon as possible, to capitalize on these early listening opportunities.

6 months

As babies grow and start to develop head control, their vocalizations become louder and more purposeful, and babble starts to develop at around the 6-month stage. Babies at 6 months are very sociable and interactive;

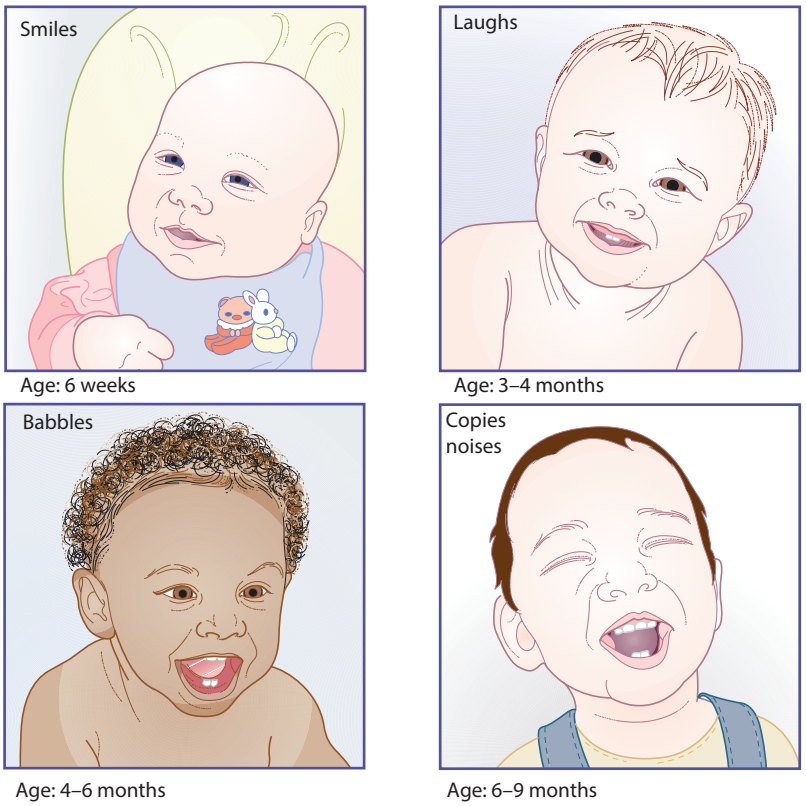

Figure 17.1 Stages in the development of speech and communication in the first 9 months.

TABLE 17.1 Stages of speech and language development in a child up to 5 years of age

Age	Listening and attention	Understanding	Speech sounds and talk	Social skills
Up to 3 months	Turns towards a familiar sound Startled by loud noises	Recognizes parent's voice Often calmed by familiar friendly voice, e.g. parents	Frequently cries, especially when unhappy or uncomfortable Makes vocal sounds, e.g. cooing, gurgling	Gazes at faces and copies facial movements, e.g. sticking out tongue Makes eye contact for fairly long periods
3–6 months	Watches face when someone talks	Shows excitement at sound of approaching voices	Makes vocal noises to get attention Makes sounds back when talked to Laughs during play Babbles to self	Senses different emotions in parent's voice and may respond differently, e.g. smile, quieten, laugh Cries in different ways to express different needs
6–12 months	Locates source of voice with accuracy Focuses on different sounds, e.g. telephone, doorbell, clock	Understands frequently used words such as 'all gone' and 'bye-bye' Stops and looks when hears own name Understands simple instructions when supported by gestures and context	Uses speech sounds (babbling) to communicate with adults; says sounds like 'ba-ba', 'no-no', 'go-go' Stops babbling when hears familiar adult voice Uses gestures such as waving and pointing to help communicate At around 12 months begins to use single words, e.g. 'mummum', 'dada', 'tete' (teddy)	Enjoys action rhymes and songs Tries to copy adult speech and lip movements Takes 'turns' in conversations (using babble)
12–15 months	Attends to music and singing Enjoys sound-making toys/objects	Understands single words in context, e.g. cup, milk, daddy, when the object was there Understands more words than they can say Understands simple instructions, e.g. 'kiss mummy', 'give to daddy', 'stop'	Says around 10 single words, although these may not be clear Reaches or points to something they want while making speech sounds	Likes being with familiar adults Likes watching adults for short periods of time
15–18 months	Listens and responds to simple information/ instructions, e.g. 'Ben, put on shoes', 'Mohammed, give to daddy'	Understands a wide range of single words and some two-word phrases, e.g. 'give me', 'shoe on' Recognizes and points to objects and pictures in books if asked Gives named familiar objects to adult, e.g. coat, car, apple, book	Still babbles but uses at least 20 single words correctly, although may not be clear Copies gestures and words from adults Constant babbling and single words used during play Uses intonation, pitch and changing volume with 'talking'	Simple pretend play Plays alone, although likes to be near familiar adult Although increasingly independent, happiest when near familiar adult
18 months–2 years	Focuses on an activity of their own choice but finds it difficult to be directed by an adult Use of child's name beginning to help them to attend to what the adult says, e.g. 'Sarah, eat sandwiches', 'Ali, put coat on'	Understanding of single words develops rapidly during this stage: between 200 and 500 words are known Understands more simple instructions, e.g. 'get mummy shoes', 'get your bricks', 'tell dad tea's ready'	Uses up to 50 words Begins to put two or three words together Frequently asks questions, e.g. the name of people and objects (towards 2 years of age) Uses speech sounds p, b, m, w	'Pretend' play developing with toys, such as feeding a doll or driving a car Becomes frustrated when unable to make self understood – this may result in tantrums Follows adult body language including pointing, gesture and facial expressions

(Continued)

TABLE 17.1 Stages of speech and language development in a child up to 5 years of age

Age	Listening and attention	Understanding	Speech sounds and talk	Social skills
2–3 years	Beginning to listen to talk with interest, but easily distracted Listens to talk addressed to him/herself, but finds it difficult if prompts are not provided, e.g. use of name, 'stop and listen'	Developing understanding of simple concepts, including in/on/under, big/little Understands phrases like 'put teddy in the box', 'get your book, coat and bag', 'draw a big brown dog' Understands simple 'who', and 'what' and 'where' questions but not 'why' Understands a simple story when supported with pictures	Uses 300 words, including descripting language, time, space, function Links four or five words together May stutter or stammer when thinking what to say Able to use pronouns (me, him, she), plurals and prepositions (in, on, under) Has problems saying speech sounds l/r/w/y, f/th, s/sh/ch/dz/j	Holds a conversation but jumps from topic to topic Interested in other's play and will join in Expresses emotion towards adults and peers using words, not just actions
3–4 years	Enjoys listening to stories Still finds it difficult to attend to more than one thing at a time, so can't easily listen to a speaker while still carrying on an activity; has to switch attention between speaker and task	Understands questions or instruction with two parts: 'get your jumper' and 'stand by the door' Understands 'why' questions Aware of time in relation to past, present and future, e.g. 'Today is sunny, yesterday was rainy. I wonder what the weather will be like tomorrow?' (towards 4 years)	Uses sentences of four to six words, e.g. 'I want to play with cars', 'What is that thingy called?' Uses future and past tense, e.g. 'I am going shopping', 'I walked home' May continue to have problems with irregular words, e.g. 'runned' for 'ran', 'swimmed' for 'swam' Able to remember and enjoys telling long stories or singing songs Has problems saying r, j, th, ch and sh	Understands turn-taking as well as sharing with adults and peers Initiates conversations Enjoys playing with peers Able to argue with adults or peers if they disagree – uses words, not just actions
4–5 years	Attention is now more flexible – the child can understand spoken instructions related to a task without stopping the activity to look at the speaker	Able to follow simple story without pictures Understands instructions containing sequencing words; 'first … after … last' Understands adjectives: soft, hard, smooth, etc. Aware of more complex humour, laughs at jokes that are told	Uses well-formed sentences, e.g. 'I played with Ben at lunchtime' but there may still be some grammatical errors Easily understood by adults and peers, with only a few immaturities in speech sounds, e.g. 'th', 't' and three-consonant combinations 'scribble' Frequently asks the meaning of unfamiliar words and may use them randomly	Chooses own friends Generally cooperates with playmates Able to plan construction and make-believe play activities, e.g. building models from Lego Takes turns in longer conversations Uses language to gain information, negotiate, discuss feelings/ideas and give options

Reproduced with permission from I Can.[5]

they can easily express their likes and dislikes through their facial expressions and vocalizations. At around this age, babies begin to understand that they can use their voices to attract the attention of their caregivers and they engage in vocal turn-taking with their carers. Hearing babies are beginning to gain meaning from what they hear at this stage – they can anticipate the arrival of a familiar person from hearing their approaching voice and they can make sense and respond appropriately to different tones of voice – so they can tell the difference between happy and angry voices, for instance. They may also respond to their name being called, and they may start to respond to 'no'.

At 6 months, babies enjoy exploring everything they can lay their hands on and most objects tend to go into the mouth. This is a particularly difficult stage for parents of young hearing-aid users as encouraging 6-month-olds to wear their hearing aids is challenging to say the least. All professionals need to support parents through this stage.

Warning signs are difficult to spot at this early age, but all professionals should be aware of the signs of possible communication difficulties. A baby of 6 months old who does not startle to loud sounds, engage in eye contact or smile back when being spoken to, or seems to lack interest in faces, may need to be seen by a paediatrician for developmental assessment.

9 months

At 9 months a baby's babbling is more advanced, with strings of both canonical babble (where the same consonants and vowels are reduplicated [*bababa*]) and non-canonical or variegated babble (where new and different consonants are introduced to the babble stream [*badabada*]). Babies with hearing are now beginning to understand familiar words and phrases, such as 'wave bye-bye', and they may even be making some early word attempts, where babble patterns such as 'mama' and 'dada' are beginning to be associated with the relevant people.

Babies at this age are starting to point to objects, which draws the adults' attention to the object and makes you name them. This is an important marker for communication development; babies who fail to develop pointing may be at risk of developmental disorders such as autistic spectrum disorder and they need to be carefully monitored.

Other important communication markers to look out for at 9 months are the child's ability to gain your attention and respond to noises. Babies who are failing to do these things, certainly by 12 months of age, may need further investigation.

12 months

Babies become toddlers around their first birthday and are also becoming great communicators! One-year-olds can understand many words and gestures and will respond accordingly. They can also initiate conversations themselves to express their wants and needs. Babies at 12 months will have a small number of words (around ten), although they will not pronounce them clearly and may only be understood by those closest to them. Intelligible speech is not something that should be expected at a year.

18 months

At 18 months toddlers are developing strong personalities and it is at this stage that there is enormous variability in children's language development. Some at this age have an extensive vocabulary and are already stringing words together into short phrases; others will still have only a small handful of words, and yet would still be classed as functioning within normal limits. Crucially, children's understanding of words and phrases is important at this age; 18-month-olds should be able to follow simple requests and point to pictures in a book and to body parts, and children who are not yet able to do this will need careful monitoring and possible referral to speech and language therapy services.

2 years

The 2-year-old's greatest achievement is their language development. A 2-year-old will have an average vocabulary of around 60 words and some two-word combinations, and they will understand many more. They will enjoy naming everything they see, and will repeat everything that they hear. At this time, adults need to focus on the meaning behind the message rather than the children's grammar and speech sounds as there will still be many errors.

It is between the ages of 2 and 3 years that speech, language and communication difficulties become more apparent, and early referral to speech and language therapy services is vital. Children of this age should be referred if:

- the child prefers to point or show what they want rather than to say it
- single words are not yet being combined into phrases or sentences
- they seem slow to follow instructions and prefer to wait to be shown what to do rather than be told
- adults, and particularly close family members, find it hard to understand what they say, either because their speech is unclear, or the language they use is confused.

3 years

A 3-year-old will be developing an understanding of the simple concepts of size, colour and position. They will also enjoy simple stories and be able to answer simple questions such as 'who…?' and 'what…?' They will have a rich and varied vocabulary of approximately 300 words, which they will be linking together into sentences of four or five words. Grammatical development will also be progressing, with children of this age starting to use grammatical markers for plurals, and grammatical words such as pronouns. Three-year-olds often stammer when talking, but this is a developmental stage which passes quickly. Their speech intelligibility is improving, although they will still struggle with certain speech sounds, or blends of sounds.

4 years

At 4 years of age, children use much longer sentences and are beginning to indicate past and future tenses, although they are likely to struggle with irregular tense constructions, so may say 'swimmed' instead of 'swam', for example. They will still have difficulties producing some speech sounds. A 4-year-old will need speech and language therapy assessment if:

- they are struggling to understand and retain language around concepts
- they are finding it difficult to talk in longer sentences, by failing to organize words into the right order or not having the vocabulary to express what they want to
- they miss out words within a sentence, for instance 'boy play ball' rather than 'the boy is playing ball'
- they are not using the right speech sounds or they miss out some sounds altogether
- they seem to have developed a stammer or dysfluent speech has persisted.

5 years

Five-year-olds are confident and competent communicators who use well-formed sentences and are easily understood by others. They are interested in language and words; they will frequently ask what words mean and are developing a verbal sense of humour.

SPEECH, LANGUAGE AND COMMUNICATION DIFFICULTIES: CAUSES AND PREVALENCE

Speech, language and communication needs may be the most common disability in children under the age of 5, with the range of estimates of prevalence across the UK population between 2% and 25%, depending on the data collection methods used and the criteria applied.[6] The speech, language and communication needs of preschool children can be many and varied, ranging from a child who presents with mild speech difficulties, to a child with no communication skills at all. These difficulties may arise as a consequence of other conditions, so children with sensory impairment, learning disabilities, physical needs or developmental disorders are far more likely than their peers to have problems communicating. However, significant numbers of children present with speech and language difficulties where there are no other factors present. Although for the majority of these children their problems may be relatively minor and easily remediated, a proportion of them will experience persistent and complex communication problems which will need specialist support for a prolonged period if they are to progress to their full potential.

An important distinction to make at this point is the difference between a language and/or speech **delay** and a true **disorder**. Speech and/or language delay is defined as 'a delay in speech and/or language development compared with controls matched for age, sex, cultural background and intelligence'.[7] The extent of the delay can vary from being fairly minor to severe and debilitating, particularly if associated with other conditions such as learning disability.

Learning difficulties

Around 2 million people in the UK have a learning disability. Mencap states that 'a learning disability is a reduced intellectual ability and difficulty with everyday activities – for example household tasks, socialising or managing money – which affects someone for their whole life. People with a learning disability tend to take longer to learn and may need support to develop new skills, understand complicated information and interact with other people'.[8]

Speech, language and communication difficulties are found in children and adults with all levels of learning difficulties, from mild through to severe and profound; the more significant and severe the learning disability, then the more likely it is for the communication difficulty to be severe, with approximately 80% of people with severe learning difficulties not acquiring speech.

Physical impairment

Children with physical impairments including cerebral palsy are likely to present with speech, language and communication difficulties. Speech in particular is often affected because of the difficulties in motor control and planning, but individuals with physical disabilities may also present with learning difficulties and sensory impairments, which can further exacerbate their communication difficulties. It is also important to mention that physical impairments of the vocal tract can cause speech difficulties. In particular, cleft palate, which is the most common congenital craniofacial abnormality, affecting about 1 in 600 live births, can cause atypical speech development and problems with resonance that can persist without specialist support and treatment.

Autistic spectrum disorder

Autism is a lifelong condition that affects how a person communicates with, and relates to, other people. It also affects how they make sense of the world around them. Autism is a spectrum disorder, which ranges from mild to profound, and communication difficulties, particularly in the areas of social communication and interaction, are crucial diagnostic indicators. The National Autistic Society suggests that approximately 700 000 people in the UK have ASD, which is 1 in every 100 people.

Sensory impairment

Childhood hearing loss is, of course, familiar to professionals working within ENT and it can have a considerable impact on communication, educational attainment, employment opportunities and quality of life. Deafness may be congenital or acquired, temporary, permanent or fluctuating and may range from a mild difficulty, where individuals may struggle a little to follow speech in noisy environments, through to a profound loss, where speech is inaccessible even with the most powerful hearing aids, and cochlear implantation may be necessary.

Over the past two decades, great advances have been made in hearing technologies, meaning that even profoundly deaf children can access spoken language in ways that were only dreamt of 50 years ago. However, there is certainly no room for complacency. Hearing technologies, although excellent, do have their limitations, especially in less than optimal acoustic conditions, and despite earlier identification of hearing loss thanks to newborn hearing screening programmes both in the UK and worldwide, a significant number of deaf children are still struggling to develop speech and language. The reasons for this are multifaceted and some of these will be beyond the control of professionals; a high percentage

(around 40%) of deaf children will have additional difficulties which may affect their ability to learn.[9] However, the importance of early and appropriate amplification is certainly something that ENT professionals need to consider.

The evidence for the importance of early cochlear implantation for the best spoken language outcomes in profound hearing loss is unequivocal, meaning that early referral to cochlear implant teams should be a priority for all ENT doctors. Many children implanted before 18 months of age show a similar rate of language development as their hearing peers. Those implanted after 3 years of age may struggle to catch up,[10] and it is recognized that a proportion of children will remain language-delayed when compared to hearing peers.[11] It is important to note, however, that children with cochlear implants consistently show a higher level of language attainment than profoundly deaf children using hearing aids (see Chapter 94, for further details).

It is worth noting here that children with visual impairments may also experience difficulties with communication. Children with visual impairments may follow a different developmental path to typically developing children, particularly in the area of social communication, as the early interactive skills of eye contact and shared attention may have been lacking. It is also very common for visual impairments to co-occur with other disabilities, meaning that these children's communication needs can be extremely complex.

Language disorders

Language disorders are identified when a child presents with a language score on standardized tests two standard deviations from the child's age and where there is no neurological, sensory, developmental or physical impairment that could account for the poor performance.[12] Language disorders can therefore be accurately diagnosed only by a process of exclusion and it is vital that thorough and comprehensive assessments are carried out to rule out the presence of other difficulties. This group of children is a significant one, with studies suggesting that 5–7% of children starting school have such a disorder. The most commonly used term to describe this condition is developmental language disorder (DLD), and children with DLD may have difficulty in only one or in a combination of language and speech areas. There is no single known cause of DLD, with both intrinsic and extrinsic factors playing a part.[13] However, genetics are known to have an influence, with evidence of strong family histories for DLD. More boys than girls present with DLD, with studies estimating ratios of around 3:1.

Speech sound disorders are distinguishable from speech delays because the children present with unusual or idiosyncratic patterns of speech production that do not follow normal developmental patterns. Children with speech sound disorders may also continue to use immature patterns for much longer than expected and may be resistant to therapeutic intervention. These children will have restricted and distorted sound systems and will have problems producing connected speech. It is important that any structural factors that may be causing or contributing to speech sound problems are investigated and ENT professionals may be asked to assess these children to check for issues such as palatal function and carry out a thorough examination of the head and neck.

HYPERNASAL SPEECH

In hypernasal speech (rhinolalia aperta) the velopharyngeal sphincter remains open or partly open during speech and air escapes into the nasal cavity. Causes include palatal paralysis (e.g. cerebral palsy), cleft palate, submucous cleft, adenoidectomy, and craniofacial surgery such as midfacial osteotomy. Placing a cold steel spatula under the nostrils and observing the misting pattern as the child speaks is a useful clinical test for the condition. Some nasal escape is normal during 'nasal' sounds such as *mm*, *nn* and *ng*, but misting when the child speaks a phrase with no nasal sounds (e.g. 'Katie's sister was six yesterday') is suggestive of palatal dysfunction. In established cases, there may be compensatory nasal grimacing as the child attempts to correct the nasal escape. Velopharyngeal insufficiency and submucous palatal clefts are discussed in Chapter 18, Cleft lip and palate.

HYPONASAL SPEECH

Hyponasal speech (rhinolalia clausa) can be caused by septal deviation, nasal polyps, gross turbinate hypertrophy, adenoids or a space-occupying nasopharyngeal lesion. The spatula test shows no escape when the child is asked to speak words with 'nasal' sounds; for example, 'Mummy and nanny are mending' will be pronounced 'Bubby and daddy are bedding'.

Tonsils, adenoids and speech

Tonsillectomy may affect the 'timbre' or resonance of the singing voice and, in the case of children who sing, it is wise to inform them and their parents of this. Adenoidectomy causes transient velopharyngeal sphincter dysfunction in about 5% of cases. This can cause troublesome rhinolalia aperta. In a small minority (0.01%) this may be long-standing.[14, 15]

Children with submucous palatal clefting – where the only external sign may be a bifid uvula (**Figure 17.2**) – should have adenoidectomy with extreme caution if at all. Partial adenoidectomy, under direct or endoscopic vision and preserving a buttress of tissue around the lateral margins, may preserve the velopharyngeal closure mechanism.[16]

Hyponasal speech due to large adenoids rarely constitutes an indication for adenoidectomy on its own. Usually there will be an independent indication for surgery, such as airway obstruction. Adenoids regress and parents should be made aware of this when giving informed consent if adenoidectomy is offered to improve the child's speech.

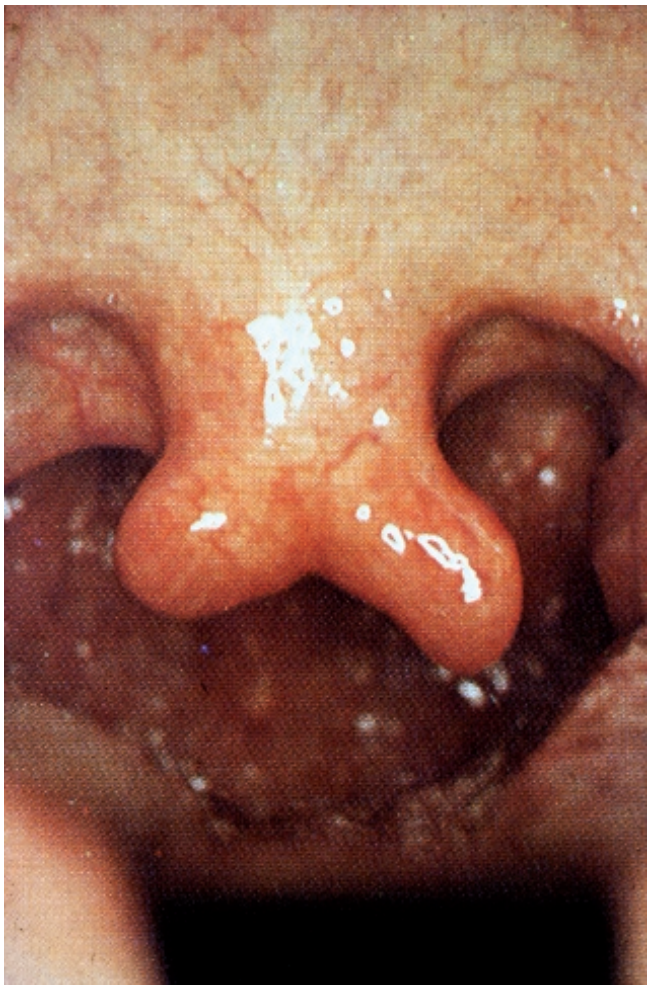

Figure 17.2 Bifid uvula – often associated with submucous cleft palate, causing rhinolalia aperta.

Figure 17.3 Tongue tie.

Tongue tie

Tongue tie (ankyloglossia) is characterized by tethering of the anterior part of the tongue to the floor of the mouth by a short lingual frenulum (Figure 17.3). It is usually asymptomatic but may restrict tongue mobility in the newborn and give rise to difficulties with breastfeeding. Many parents present for treatment as they are concerned about the appearance of the tongue or about the potential for the condition to interfere with activities such as licking the lips and kissing. The condition tends to improve as the child gets older. There is no evidence to link tongue tie with speech and language disorders. Nevertheless, parents often request treatment. If treatment is required, a simple division of the frenulum is adequate. In the newborn, this can be undertaken without anaesthesia but older children require a general anaesthetic.

ROLE OF THE SPEECH AND LANGUAGE THERAPIST

Speech and language therapy aims to help all children and adults to communicate as well as possible. All speech and language therapists (SLTs) practising in the UK are trained to at least graduate level and are registered with the Health Professionals Council. There are around 10 000 speech and language therapists working in the UK. Many of them are employed by the NHS, but some work for education authorities, for charities or in independent practice.

All SLTs understand how children's language, speech and communication develop, the difficulties that can arise, and how to help. Specialist therapists with more knowledge and experience of working with complex cases or specific conditions may also be employed, to help the local therapists plan appropriate interventions for the child and, in some cases, to see the child themselves for therapy. ENT professionals may come into contact with these specialist SLTs in fields such as deafness, where they are mainly involved in supporting children with severe to profound hearing losses, in cleft palate teams and in supporting children with voice problems.

Broadly, SLTs take responsibility for the assessment, diagnosis and treatment of children with speech, language and communication needs, and they may also be responsible for the assessment and treatment of swallowing disorders, if appropriately trained. The type of speech and language therapy a child receives will depend on many factors, including the child's needs and age, and the causes and severity of the problem(s). Therapy packages may include group or individual sessions, or assessment and advisory sessions with programmes of work being carried out by the family or school staff. All speech and language therapists are expected to work closely and collaboratively with other agencies and professionals who support the child, in particular those working in education who see the children frequently and are well placed to support the child's speech, language and communication needs in everyday settings.

For preschool children in particular, the parents will be the main focus of SLT support, as parents are always the child's first teachers, certainly as far as speech and language development is concerned. Research has shown that parents use on average over 12 000 words every day with their normally developing 2-year-olds and that the parents of the best talkers talk significantly more.[17] Interestingly, work carried out by the Lena Research Foundation showed

that the level of parental education does not predict the amount the adult speaks to the child, but gender and birth order does seem to have an effect, with girls being spoken to more than boys and firstborns hearing more talk than their younger siblings.[18] SLTs therefore play a major role in raising awareness of the importance of talking to children, and working with parents of young children with speech, language and communication needs to ensure that true progress happens within the home, not in the clinic.

The easy-to-use 'progress checker' on the Talking Point website[18] is helpful for ENT professionals in the process of deciding when to refer a child to speech and language therapy services. Other useful organizations/websites are listed below in 'References' and 'Further information'.

KEY POINTS

- Communication, speech and language difficulties can occur in isolation, or with associated conditions.
- Left untreated, speech, language and communication difficulties can have pervasive and long-term effects on the individual, including low academic attainment and offending behaviour.
- All ENT professionals should understand developmental milestones for speech and language acquisition, to ensure appropriate and timely referral to Speech and Language Therapy services.

CHAPTER 18

CLEFT LIP AND PALATE

David M. Wynne and Louisa Ferguson

SEARCH STRATEGY

Data in this chapter may be updated by a PubMed search using the following keywords: cleft lip, cleft palate, velopharyngeal dysfunction, Pierre Robin sequence, otitis media with effusion and sleep disordered breathing.

INTRODUCTION

Cleft lip and cleft palate are the commonest form of orofacial clefting. Patients with a cleft of the lip or palate have multiple ENT problems and can present to the otolaryngologist with airway, hearing, speech or nasal issues. This chapter aims to describe the epidemiology and aetiology of cleft lip and palate, and the principles of treatment, particularly in regard to ENT-related issues.

CLEFT TYPES AND CLASSIFICATION

Orofacial clefts are generally classified by laterality and extent of the defect. Cleft lip is defined as a cleft of the structures anterior to the incisive foramen, also known as the primary palate (Figure 18.1). Cleft lip can be complete (involving the alveolus), incomplete or microform. It can also be unilateral or bilateral, and may or may not involve the palate. Cleft palate is clefting of the secondary palate and may be incomplete or complete, bilateral or unilateral, or submucous.[1] Cleft lip ± palate (CL±P) and isolated cleft palate/cleft palate only (CPO) are unique in both their aetiology and epidemiology.

Various classification systems have been devised over the years to try to account for the variability in clefting of the lip and palate. Veau's 1931 classification[2] is commonly utilized (Table 18.1), although it is incomplete since it makes no provision for isolated cleft lip.

In the 1950s Kernahan and Stark proposed an embryologically based system centred on clefting in relation to the

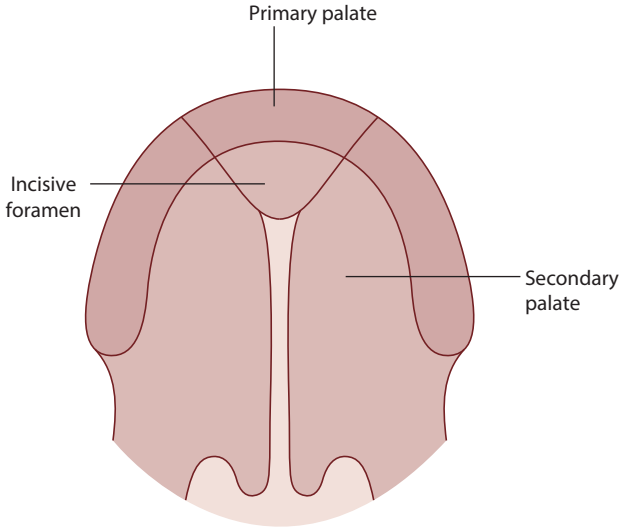

Figure 18.1 Primary palate anterior to the incisive foramen. Secondary palate, posterior to the incisive foramen.

TABLE 18.1 Veau's 1931 classification of cleft lip and palate[2]

Group	Description
Group I (A)	Defects of soft palate only
Group II (B)	Defects involving the hard palate and soft palate, extending not further than the incisive foramen
Group III (C)	Defects from the soft palate to the alveolus (usually involving the lip)
Group IV (D)	Complete bilateral clefts

incisive foramen. This was modified by Kernahan in 1971[3] who proposed a system based on the intraoral view of the palate. A 'Y' diagram representing the cleft is marked from 1 to 9, with the relevant areas marked dependent on the extent of the clefting (Figure 18.2).

The LAHSHAL system is commonly utilized in the UK (Figure 18.3). It involves recording the cleft status starting on the right-hand side and working from the lip back to the soft palate and then forward again on the left and marking each area as complete (C), incomplete (I) or no cleft (X). The areas are subdivided into lip, alveolus, hard palate and soft palate.

EPIDEMIOLOGY

Cleft lip and cleft palate are the commonest form of orofacial clefting. CL±P and isolated cleft palate are two separate entities in terms of both aetiology and epidemiology. The overall incidence of orofacial clefting is between 1 in 600 and 1 in 750, which amounts to around 1000 new cases a year in the UK.[1] CL±P incidence varies with ethnicity and race. The Asian population have the highest incidence with approximately 2 per 1000. The white population have an incidence of 1 in 1000 and the lowest incidence is in the Afro-Caribbean population, which has an incidence of 0.3 per 1000 live births.[1,4] CL±P is more common in males and 80% are unilateral, with a left to right ratio of 2:1.[1] Isolated cleft palate is not affected by race and has an overall incidence of 1 in 1500. Cleft palate alone is twice as common in females.[5] The typical distribution of orofacial clefts is cleft lip and palate 46%, cleft palate only 33% and cleft lip alone 21%.[6]

AETIOLOGY AND GENETICS

Orofacial clefts may be syndromic or non-syndromic. Most orofacial clefts are non-syndromic and occur as an isolated anomaly. CPO is more commonly associated with a syndrome than CL±P, with a recent systematic review estimating around 50% for CPO 30% for CL±P.[7] There are now over 400 syndromes associated with CPO and CL±P in the London Dysmorphology Database,[8] with some of the more common syndromes listed in Box 18.1.

The most frequent interstitial deletion in humans is del(22)(q11.2), with an estimated prevalence of 1 per 4000 live births.[9] This deletion is associated with a wide phenotypic spectrum including the Di George and velocardiofacial phenotypes. Approximately half of the cases of 22q deletion will have a palatal abnormality, most commonly submucous cleft palate or CPO. These children can also

Maternal age
Maternal smoking
Maternal obesity (BMI>30)*
Prepregnancy diabetes*
First trimester heavy alcohol consumption
Medications (anticonvulsants, folate antagonists, retinoic acid)*
White non-Hispanic race*
Sex*

**Also associated with CPO.* Data from Watkins et al. 2014.[9]

have non-cleft velopharyngeal dysfunction due to a deep post-nasal space secondary to a wide skull base angle. Any patient with a palatal defect, and any other manifestation of 22q11 (cardiac malformation, neurodevelopmental delay, immunodeficiency) should be screened, as prevalence can be as high as 40%.

Non-syndromic clefting is multifactorial and is influenced by both genetic and environmental factors. Non-syndromic clefting may have a known or unknown cause. Variants of the *IRF6* gene (interferon regulatory factor 6) can cause a Mendelian type inheritance, notably Van der Woude syndrome, but variants of *IRF6* have also been implicated in non-syndromic orofacial clefts.[7] Genome-wide association studies have provided insights into the genetic background of non-syndromic CL±P and contributing genes include aberrations in *TGF-b3*, *NAT 1TBX22*, *MSX1* and *FGFR*.[9–12]

Environmental factors which contribute to facial clefting are varied, and many are still under evaluation (**Box 18.2**). Alcohol consumption, particularly in the first trimester, is known to be a risk factor.[13, 14] Maternal smoking also increases the risk of orofacial cleft,[15–19] with a population-attributable risk of up to 20%.[15, 19] Anticonvulsant drugs[20–22] increase risk of cleft palate and positive associations with maternal corticosteroid use in pregnancy have also been reported in the literature, although this is less clear-cut.[23] Low B-complex vitamins, folic acid deficiency[24] and maternal obesity[25] also have some links to clefting, although further research is needed to define these risks more clearly.

If a primary relative has a facial cleft the chances of the child having a cleft, in the absence of a defined syndrome, is 3.5%.[26] This decreases with secondary and tertiary relatives. For parents who already have a child with an orofacial cleft, the risk of a subsequent child having a cleft is around 2–5%.

EMBRYOLOGY

An understanding of the embryology responsible for the development of the cranium and face is important as it allows us to understand why CL±P and CPO are different entities. The five main prominences responsible for development of the face are the frontonasal prominence, the paired right and left maxillary prominences and the right and left mandibular prominences. Incomplete or aberrant timing of fusion of the frontonasal and maxillary prominences results in cleft lip and/or palate (**Figure 18.4**). The frontonasal prominence is split into medial and lateral nasal prominences by development of a nasal pit on the ventrolateral aspect of the frontonasal prominence. Formation of the lip occurs between the fourth and sixth weeks of gestation when the bilateral maxillary prominences fuse with the medial nasal prominence to form the lip and alveolus. The secondary palate begins to form during the sixth week of development as the palatine shelves, which are outgrowths from the maxillary prominences, advance obliquely downward to lie horizontally over the tongue. The palatine shelves fuse with the previously formed primary palate and then from anterior to posterior the palatine shelves fuse in the midline, so that by week 12 the palate is intact. Failure of any of these processes can result in clefting (**Figure 18.5**).

FUNCTIONAL ANATOMY

Anatomical anomalies of the lip, palate, septum, external nose and other midline structures can affect patients with a cleft lip and plate.

Lip

Integrity of the lip and oral sphincter is important for normal function of the mouth. A defect in the lip results in abnormal insertion of orbicularis oris and loss of continuity of the vermilion border, both of which have to be addressed in cleft lip repair in order to allow long-term return to form and function. The mucocutaneous area of the lip is well defined into three regions: there is the cutaneous skin of the upper lip and philtrum, an intermediate area of dry mucosa known as the vermilion and an internal area of moist mucosa.[27] The orbicularis oris normally forms a full sling under the mucosal covering, however aberrant muscle due to the cleft results in insertion of the orbicularis oris into the dermis and nasal ala on the cleft side and insertion into the columella on the non-cleft side (Figure 18.6).

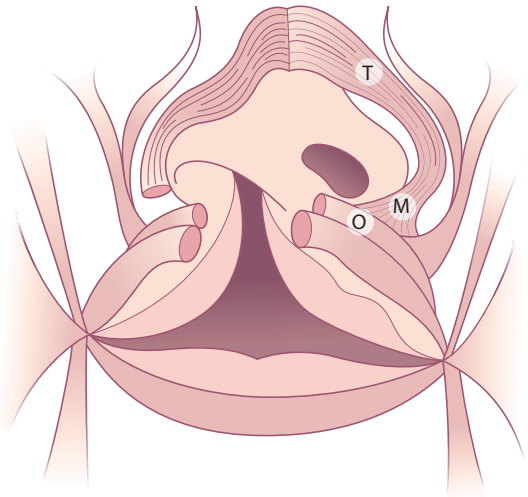

Figure 18.6 Nasolabial muscle ring in unilateral cleft lip. M, myrtiform head of nasalis muscle; O, oblique head of orbicularis oris; T, transverse head of nasalis muscle.

Nose

Abnormality of insertion of the orbicularis oris contributes to the nasal deformity seen as part of cleft lip. By inserting into the nasal alar base there is outward splaying of the lower lateral cartilage, which results in the alar base on the cleft side sitting more lateral and inferior than it should. This results in a differing shape and position of the lower lateral cartilage on the cleft side, with shorter medial crus and longer lateral crus, and a classically flattened and wider dome on the cleft side. The columella is shortened and the anterior cartilaginous septum deviated to the non-cleft side, due to the unopposed pull of the orbicularis oris on the columella. This allows bowing of the septum onto the cleft side more posteriorly and, along with the reduction in the nasal valve area due to lower lateral cartilage abnormalities, the overall nasal airway is restricted. Nasal airflow resistance is known to be higher in patients with CL±P by around 20–30%.[28, 29]

Palate

Clefts of the palate are associated with bony and soft-tissue abnormalities. Adequate closure of the velopharyngeal port for speech and swallowing is the aim of palate repair. The primary velar muscles are the levator veli palatini, palatopharyngeus and palatoglossus (Figure 18.7). The levator

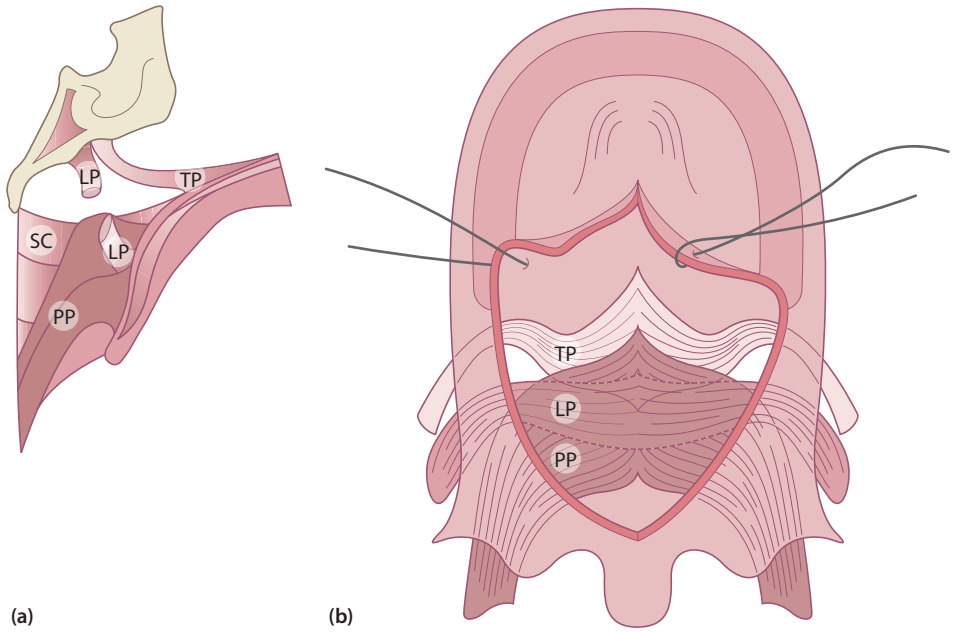

Figure 18.7 Velum muscles. **(a)** Sagittal view from midline; **(b)** inferior view. LP, levator palatini; PP, palatopharyngeus; SP, superior constrictor; TP, tensor palatine.

veli palatini muscle is the primary elevator of the palate. It originates from the medial part of the Eustachian tube and from the petrous temporal bone and runs anteriormedially to enter the middle third of the velum between the two heads of palatopharyngeus to join with its partner from the opposite side, and form the levator sling. In patients with a cleft palate the levator veli palatini no longer has this transverse orientation, but instead the muscle is longitudinally orientated and inserts into the bony cleft margin and posterior palatine bones. The palatoglossus and palatopharyngeus arise from the back of the palatal aponeurosis and maxillary tuberosity. The palatoglossus is a thin sheet of muscle that extends to form the anterior tonsillar pillar. The palatopharyngeus is a more substantial muscle that is split into two heads by the insertion of the levator veli palatini and runs down to form the posterior tonsillar pillar and inserts into the thyroid cartilage and pharyngeal aponeurosis. The palatopharyngeus and palatoglossus act as depressors and, along with the levator veli palatini, these muscles act to lengthen the velum. The final muscle to consider is the tensor veli palatini, whose primary function is opening of the Eustachian tube. Its fibres originate from the sphenoid spine, scaphoid fossa and lateral lamina of the Eustachian tube cartilage,[30] and form a tendon which winds round the pterygoid hamulus and spreads into a fibrous aponeurosis in the anterior third of the soft palate.

ENT ISSUES

Airway

All children are obligate nasal breathers for the first few months of life. This is due to the high position of the infantile larynx that gradually descends. In the neonate the anterior epiglottis can often be easily seen in the oral cavity behind the soft palate. This superior position of the larynx allows the infant to suckle.

There are many congenital anomalies associated with cleft lip and palate, and one of the most commonly seen in ENT is Pierre Robin sequence (PRS). In PRS micrognathia and glossoptopsis may result in upper airway obstruction (Figure 18.8).

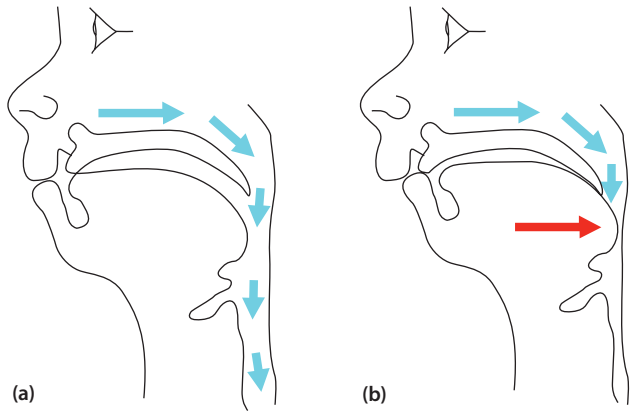

Figure 18.8 Diagrams showing **(a)** normal airway in an infant; **(b)** where retro-position of the mandible has resulted in the tongue blocking the airway.

NEONATAL PERIOD

Upper airway obstruction can happen immediately following delivery or can develop progressively over weeks or months of life. The Royal College of Paediatrics and Child Health (RCPCH) respiratory subgroup recommends that all children with craniofacial disorders including PRS undergo overnight oximetry, preferably in combination with measuring CO_2, within the first 4 weeks of life.[31] Children with PRS may have worsening obstruction between 4 and 8 weeks of age, and reassessment may be required during that time. Otherwise, further studies should be performed at 3–6-monthly intervals during the first year of life, and thereafter according to clinical symptoms. Often children with PRS have their palate surgery delayed until around 18 months of age to allow their airway obstruction to improve.

Treatment options for airway obstruction in these children, depends on the severity of symptoms. The options can be divided into two main subgroups, non-surgical and surgical, as listed in Box 18.3.

POST-OPERATIVE PERIOD

Any airway issues tend to happen within 24–48 hours of surgery. They are usually associated with palatal surgery or pharyngoplasties but on occasion can occur following lip repair or anterior rhinoplasty. Children are often placed in an HDU following primary lip and palatal surgery to allow careful monitoring in the early post-operative period. This allows close monitoring of the child and early intervention if the child develops any signs of respiratory distress.

LONG-TERM SLEEP-DISORDERED BREATHING

All cleft children have the same risk as other children with regard to sleep-disordered breathing and obstructive sleep apnoea (e.g. secondary to adenotonsillar hyperplasia). They may, however, be at higher risk due to their anatomical abnormalities being corrected and narrowing the nasopharynx.

A pharyngoplasty is performed to reduce the nasopharyngeal airway to help prevent nasal escape during speech. This has the potential detrimental effect of increasing the likelihood of apnoeic episodes. Careful pre-operative discussion and patient evaluation within the multidisciplinary team setting should be undertaken to discuss the risks versus benefits of such a procedure. The complications of chronic obstructive sleep apnoea (OSA) include hypoxemia, hypercarbinemia, neuropsychiatric problems and decreased cognitive function. In severe cases the chronic obstruction can result in pulmonary hypertension and cardiac failure. There is also a link between OSA in childhood and adult hypertension.

BOX 18.3 Treatment options for airway obstruction

Non-surgical	Surgical
Nasopharyngeal airway	Tongue–lip adhesion
CPAP	Tracheostomy
	Mandibular distraction

Hearing loss

As in all children, hearing loss in CL±P patients can be conductive, sensorineural or mixed.

Otitis media with effusion (OME) is almost ubiquitous with CL±P. Approximately 97% of cleft children are thought to have had an episode of OME by the age of 2,[32] with the incidence reducing with increasing age.[33] The aetiology behind the increased incidence of OME is thought to be due to Eustachian tube dysfunction secondary to the malposition of the tensor veli palatini muscle, as mentioned previously.

In the recent past this has led to the 'routine' insertion of ventilation tubes at an early age, usually at the time of palatal repair. However, as more data have been collected about the incidence and prevalence of the otological sequelae of OME, a much more selective approach has been introduced. Recent systematic reviews[32, 34] have shown there was insufficient evidence to determine if early ventilation tube placement had any benefit on either hearing or speech development, and that further studies in this area are warranted. Currently in the UK the Cleft Collective research group is undertaking the MOMENT trial (The Management of Otitis Media with Effusion in Children with Cleft Palate) to try to acquire more guidance on the optimum management of OME in CL±P patients.[35] As we know, not all episodes of OME will result in a hearing loss or damage to the middle ear. Current recommendations in the UK are found in NICE60.[36] Essentially, a persistent CHL associated with OME in excess of 25–30 dBHL or OME affecting a child's developmental, social or educational status should be offered treatment. The treatment options should include ventilation tube insertion or provision of hearing aids. Primary ventilation tube insertion is only recommended after careful ENT/audiology assessment in children with a cleft palate.

In the UK cleft care is closely audited and minimal standards of care have been agreed. Routine hearing testing is taken at 6 months, and 1, 2, 3, 4, 5, 10 and 15 years of age. Ensuring adequate hearing thresholds allows normal verbal communication to develop. This is important in the CL±P population as learned 'cleft type' speech cannot be corrected at an older age.

Long-term middle ear disease has also been reported to be higher in the cleft population due to persistence of Eustachian tube dysfunction following palatoplasty. Retraction pockets and subsequent development of cholesteatoma has been found to be higher in the cleft population[37–41] and ongoing otologic assessment in these patients is important.

MANAGEMENT

Care of a child with a cleft lip or palate is a complex, highly specialized and lifelong undertaking. Deficiencies of speech, facial growth, cosmetic appearance, hearing and dental problems require that this care is addressed in a multidisciplinary setting in order to allow adequate attention to all aspects of care and subsequently improve outcomes.[42] Input is needed from a cleft surgeon, otolaryngologist, paediatric dentist, specialist nurse, speech therapist, psychologist, audiologist, orthodontist, geneticist and paediatrician.

During the management of children with a cleft lip and palate, areas to be addressed are:

- speech
- hearing
- appearance
- dental growth and hygiene
- psychosocial health.

Diagnosis

Prenatal diagnosis of cleft lip and palate has allowed around 75% of children to be picked up as early as 13–16 weeks' gestation by ultrasonography.[43] Isolated cleft palate cannot be as easily detected prenatally, but the role of prenatal foetal MRI in further diagnosing palatal clefting may become more frequent in the future.[43] Following diagnosis, the parents should be referred antenatally to the cleft team so that appropriate support can be provided. Advice can be given on feeding, expectations of treatment protocols and details of parental support groups. After birth the specialist cleft nurse will make contact within the first 24 hours to give support and help establish feeding. Children with a cleft lip and palate may be able to breastfeed with help, or the use of specialized bottles (Haberman) may be more helpful, as the ability to create a vacuum to suckle milk is reduced.

Surgical management

Surgical management of cleft lip and plate is complex and tailored to the individual deformity present. There are numerous techniques across the world to deal with orofacial clefts and the detailed surgical steps of each procedure are beyond the scope of this chapter. The principles of surgical management are covered. Table 18.2 summarizes the timings of surgical management options.

TABLE 18.2 Surgical management from birth to adulthood

Age	Procedure
3–6 months	Primary lip ± nose repair ± hard palate
9–12 months	Palate repair ± ventilation tubes
4–5 years	Secondary speech surgery (if required)
8–10 years	Alveolar bone graft (if required)
15–18 years	Secondary rhinoplasty
16 years +	Orthognathic surgery (if required)

PRESURGICAL ORTHOPAEDICS AND NASOALVEOLAR MOULDING

Nasoalveolar moulding (NAM) is a form of presurgical infant orthopaedics designed to reduce the severity of the cleft deformity and move the nasal alar cartilages into a more favourable position. Attempts to reduce the severity of the cleft are not a new phenomenon and various devices have been used in the recent past. NAM involves using an oral plate, which is individually moulded with nasal stents attached, to try to achieve these aims. The device is fitted as soon after birth as feasible and is worn fulltime. It is regularly adjusted to alter the shape and length of the nasal cartilages and columella. The research on whether NAM successfully achieves these outcomes remains inconclusive,[44] although some studies show positive results,[45–47] particularly in improving nasal symmetry in the unilateral cleft lip and palate patients.[48] Randomized controlled trials at a national level are lacking and, although NAM is gaining support particularly in North America, it is yet to be incorporated into routine UK practice.

LIP REPAIR

Repair of the cleft lip aims to address both functional and cosmetic problems. In the UK the lip is generally repaired when the child is 3–6 months of age, along with the hard palate and primary nasal surgery, dependent on requirements. Neonatal lip repair is performed in some centres, although no firm evidence of aesthetic or functional benefit yet exists.[49, 50] The aims in both unilateral and bilateral cleft lip repair are similar: to achieve primary muscle continuity and reconstruct the lip elements to give a symmetrical-appearing Cupid's bow with the minimum of scarring. The importance of reconstructed musculature in achieving optimal results is well reported and should be adequately addressed at the time of lip repair.[51–56]

Bilateral cleft lip is a more severe deformity than unilateral and achieving muscle continuity across the projected premaxilla can be a challenge. The use of lip adhesion (taping of the lateral lip segments to the premaxillary segment) and single-sided staged surgery have been advocated in an attempt to facilitate lip repair, but neither of these approaches is supported in the literature. There are multiple approaches to reconstructing the skin of the lip, the Millard repair and its modifications, and the Fisher repair being the two most commonly practised in the UK.

PALATE REPAIR

Hard palate

Timing of palatal closure is variable between centres, and there is a trade-off between early palatal closure to help speech, and delaying hard palate closure to improve facial growth. In the UK it is common practice to close the hard palate with a vomerine flap at the time of lip repair in a complete cleft lip and palate, or close with the soft palate repair in an isolated cleft palate patient.

Soft palate

The aim of palatoplasty is to reorientate the palatal muscles in order to achieve lengthening and improve movement of the palate in order to create adequate velopharyngeal closure. There are various surgical options available to the cleft surgeon, each of whom will have their preference. The intravelarveloplasty, popularized by Sommerlad, involves radical dissection of the velar muscles and reorientation to a transverse position to recreate the anatomical levator sling.[57] The nasal and oral mucosa are dissected from the muscles and repaired over the newly formed sling to close the cleft (**Figure 18.9**).

The Furlow palatoplasty uses a double opposing Z-plasty technique to lengthen and reorientate the muscles. This method results in posterior repositioning of the velar muscles, albeit with a degree of asymmetry, and results in some degree of palatal lengthening. Both techniques have been shown to have good speech outcomes[58, 59] and there has been no difference found in audiological outcomes between the techniques.[60]

NASAL SURGERY

Nasal surgery in a patient with a cleft lip and palate aims to improve aesthetics and nasal airflow, in a timely fashion but with the minimum of disruption to facial growth. Cleft nose deformity is characterized by an asymmetric nasal tip, deviated septum and asymmetry of the nasal bones. Timing of nasal surgery is somewhat controversial. Given the complexity of cleft nasal deformities, definitive rhinoplasty is often reserved until adolescence and completed facial skeletal growth, however evidence has shown that stable long-term results with limited growth disturbance can be achieved with primary rhinoplasty.[61–64]

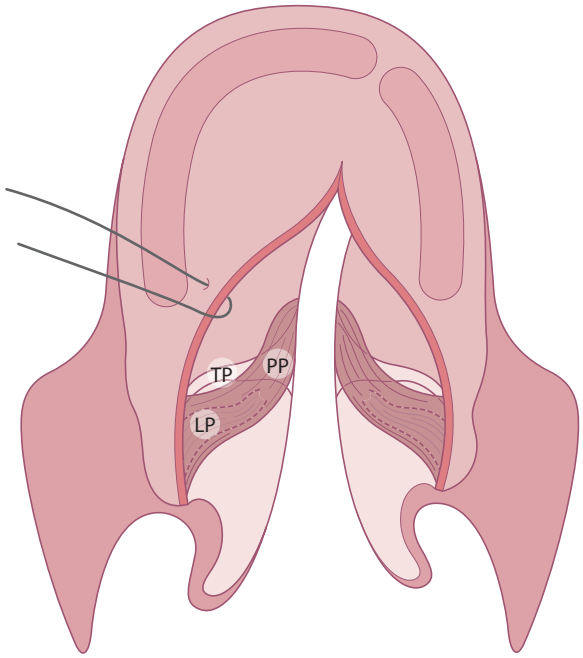

Figure 18.9 Cleft palate muscles. LP, levator palatini; PP, palatopharyngeus; TP, tensor palatini.

ALVEOLAR BONE GRAFTING

Some children will require alveolar bone grafting as a secondary procedure to stabilize the alveolar arch and allow eruption of the lateral incisor and canine into an optimal position. There is good evidence that secondary alveolar bone grafting produces consistently good results.[65, 66] Timing of the bone graft is usually determined by the development of the canine tooth, although earlier bone grafting may be indicated to support the eruption of the lateral incisor. There is no evidence that secondary bone grafting has a detrimental effect on facial growth when performed between 9 and 11 years of age. This is in contrast with primary bone grafting carried out before 2–3 years of age where evidence from retrospective case series suggests that these early bone grafts were associated with significant growth impairment.[67, 68]

SPEECH AND VELOPHARYNGEAL INSUFFICIENCY

Velopharyngeal insufficiency (VPI) can occur in children with a repaired cleft palate, those with a submucous cleft and in children without any obvious palatal abnormalities. It can also occur after adenoidectomy, with a reported clinically significant incidence of between 1 in 1500 and 1 in 3000. Stigmata of a submucous cleft are bifid uvula, zona pellucida and hard palate notch, all of which should be examined for at the time of adenoidectomy. VPI occurring after adenoidectomy will spontaneously resolve in about 50% of cases.[69] In order to achieve intelligible speech, the palate must be able to seal against the posterior pharyngeal wall and close off the nasopharynx. If this is impaired, nasal emissions and hypernasal speech can ensue. Around 20% of cleft palate children have persistent speech disorder following surgery, falling into the worst category of intelligibility.[70]

Treatment for velopharyngeal insufficiency includes speech therapy and palatal or pharyngeal surgery, dependent on the degree of VPI, underlying aetiology and age of the patient. In children with a submucous cleft, management is indicated only if symptoms of VPI occur. Assessment of VPI is best performed in a multidisciplinary environment. Examination of the mouth, concentrating on the integrity and movement of the soft palate and the tonsils, which rarely if hypertrophied may be interfering with palatal closure. Nasal examination and assessment of nasal patency should be performed. Standardized tests to assess articulation and intelligibility are performed by speech and language therapy.[70]

Flexible nasoendoscopy is fast becoming the investigation of choice to assess velopharyngeal port closure objectively. Speech videofluoroscopy is also widely used by many teams and can be an alternative if nasoendoscopy is not tolerated. Both investigations provide information and so far research has not shown superiority of one over the other,[71] although nasoendoscopy may provide a closer correlation with VPI severity.[72]

Management decisions come down to underlying symptoms and the size and location of the velopharyngeal gap. Palatoplasty may be indicated to treat VPI, either as a re-repair where there is evidence of anterior insertion of the levator muscles, or in the case of a submucous cleft. It is mainly used where the velopharyngeal gap is small[73, 74] and has been shown to have a lower morbidity than a pharyngoplasty.[75] Pharyngoplasty involves altering the shape of the velopharyngeal port in order to allow closure on speech. This can be done either by using flaps from the midline of the pharyngeal wall or by employing medial transposition of flaps from the lateral pharyngeal wall. Both types of pharyngoplasty have been shown to improve speech outcomes, with the possibility of achieving normal resonance in up to 85% of cases. The main downside to pharyngoplasty is the associated increased risk of sleep apnoea, and this must be discussed with the patient and their family pre-operatively.

KEY POINTS

- Clefts of the lip and palate are common congenital birth anomalies.
- Aetiology is multifactorial. Known associations are with maternal smoking and alcohol and antenatal anticonvulsants.
- Prenatal screening for cleft lip and palate is now routinely available in many centres.
- Management of patients with cleft lip and palate requires a multidisciplinary approach to ensure the best outcomes.
- Otitis media with effusion is a significant problem in cleft palate children and further research is required to identify best practice for management.

CHAPTER 19

CRANIOFACIAL SURGERY

Benjamin Robertson, Sujata De, Astrid Webber and Ajay Sinha

SEARCH STRATEGY

Data in this chapter may be updated by a PubMed search using the keywords: craniofacial, craniosynostosis, OAVS, Treacher Collins, Apert, Crouzon, Pfeiffer, encephalocele, distraction osteogenesis, facial cleft, scapocephaly, trigonocephaly, brachycephaly and plagliocephaly.

INTRODUCTION

Craniofacial surgery is the medical specialty that diagnoses and manages complex congenital and acquired conditions of the craniofacial skeleton and associated structures. Patients with such conditions vary in their development and phenotypic presentation. Traditionally, these were thought of as congenital conditions but the term can be all-encompassing.

Due to the complexity of patients with craniofacial conditions, their treatment is required to take place in a multidisciplinary unit. Table 19.1 shows the specialties that comprise the multidisciplinary team (MDT) with their roles.

Treatment often lasts from the perinatal period, well into adolescence and often into early adulthood.

Owing to the complexity and heterogeneity of craniofacial anomalies there is no universal classification system. Many classification systems have been proposed, based on embryology, aetiology, anatomical location, morphology and genetics. In England, the National Commissioning Group recognizes six categories of patient:[1]

- craniofacial clefts
- craniofacial dysostosis
- craniosynostosis
- encephalocoele
- overgrowth, undergrowth or dysraphia associated with unilateral or bilateral orbital dystopia or displacement
- any other complex anomaly where referring specialists feel that the expertise present within the service would substantially benefit the treatment of the condition.

There are multiple other conditions of the craniofacial region that, although not specified in this classification, are often treated in these units due to the expertise of the clinicians involved. Currently in England and Wales, there are four units commissioned to treat the above conditions:

- Alder Hey Children's Hospital, Liverpool
- Birmingham Children's Hospital
- Great Ormond Street Hospital, London
- Oxford University Hospital.

The aim of this chapter is to describe the more commonly encountered groups of craniofacial anomalies, to outline the principles of their management and to review the role of the ENT surgeon in managing these patients. The genetic contribution to these conditions will also be discussed.

TABLE 19.1 The craniofacial team

Discipline	Role
Maxillofacial surgery	Surgical correction of deformity
Plastic surgery	Surgical correction of deformity
Neurosurgery	ICP, hydrocephalus, associated abnormalities, combined surgical treatment of the condition
Ophthalmology	ICP, acuity and motility, corneal protection
ENT (+ audiology)	Airway + nasal problems, hearing and middle ear disease
Anaesthetist	Experience of paediatric craniofacial and neurosurgical anaesthesia Access to paediatric intensive care unit (PICU)
Genetics	Diagnosis, associated conditions, risk of future siblings having the condition, risk of patient passing on the condition to his/her children
Speech and language therapist	Speech and language, feeding, general developmental milestones
Psychologist	Parental anxiety, preparation for operations, intervention for older patients, coping strategies, cognitive assessment
Paediatrician	General development, associated abnormalities
Orthodontist	Craniofacial growth and development, dental condition and occlusion
Specialist nurses and coordinators	Coordinating day-to-day activities/ advice/wound management

CRANIOSYNOSTOSIS

Craniosynostosis is the premature fusion of one or more sutures of the skull. This can occur as **primary** or **secondary synostosis**. The differentiation is paramount as treatment options differ greatly. In order to understand the pathophysiology of craniosynostosis, normal skull growth must be considered.

Normal skull growth

The stimulus for growth of the cranium comes from the expanding brain, which grows rapidly in the first 2 years of life, doubling in weight in the first year and achieving 90% of its adult size by the age of 2 years. This rapid brain growth has to be accommodated by a concomitant expansion in volume of the skull. The cranial vault consists of the frontal, parietal, temporal and occipital bones, which are separated from each other by the cranial sutures (metopic, sagittal, coronal and lambdoid). These sutures allow gradual displacement of the individual bones, allowing the brain to expand. In order to avoid large gaps developing between the bones as the expansion proceeds, new bone is deposited at the free margins of the bones adjacent to the sutures. Bone resorption and deposition also take place on the inner and outer surfaces of the calvarial bones to produce changes in their curvature and thickness.

The patent cranial sutures therefore allow for growth to take place in response to the stimulus of the growing brain and, unlike the epiphyseal plates of the long bones, cranial bones do not have intrinsic growth potential. The sutures only remain patent while brain growth is taking place. If brain growth ceases, cranial growth ceases, and the cranial sutures will be replaced by bone, resulting in fusion – a normal phenomenon once growth is complete.

Classification

Premature fusion of calvarial sutures has a variety of underlying causes, broadly divided into primary and secondary craniosynostosis.[2]

Secondary craniosynostosis is uncommon, but may be seen in microcephaly, where there is a lack of underlying brain growth, in some haematologic (polycythaemia, thalassaemia) and metabolic abnormalities (rickets, hyperthyroidism), and may be drug-induced (retinoic acid).

Primary craniosynostosis is much more common than secondary craniosynostosis. It can be classified on the basis of the number of sutures involved (single-suture, multiple or total), the site of the involved suture(s) (metopic, coronal, sagittal, lambdoid) and whether it is an isolated condition (non-syndromic) or associated with other malformations (syndromic). Primary craniosynostosis constitutes a significant workload in craniofacial units.

Incidence

Primary non-syndromic craniosynostosis occurs in approximately 1:2000 live births. Of the non-syndromic craniosynostoses, sagittal synostosis is the most common, accounting for approximately 60% of cases. In cases of non-syndromic craniosynostosis there is a male predominance with male to female ratios of 4:1 in sagittal synostosis and 3:1 in metopic synostosis. Of the syndromic craniosynostoses, Crouzon syndrome has the highest incidence, with 1:25 000 live births[3] and Apert syndrome in 1:60 000 live births.[4]

Aetiology

Craniosynostosis is aetiologically heterogeneous.[4] Both non-syndromic and syndromic craniosynostoses result from an interaction between genetic factors, molecular and cellular events, mechanical and deformational forces and secondary effects of each of these on normal growth and development. Premature fusion of the sutures may take place alone or, in syndromic craniosynostosis, with other anomalies. Most cases of isolated craniosynostosis are sporadic. However, familial cases do occur and a positive family history can be found in 14.4% of coronal, 6% of sagittal and 5.6% of metopic synostosis cases, but very rarely in lambdoid synostosis.[5–9] For isolated, single-suture synostosis with unaffected parents, the recurrence risks range from 1% in sagittal synostosis to 5% in coronal and metopic synostosis.[10]

Chromosomal abnormalities may also cause craniosynostosis, particularly in patients with other anomalies or problems with growth or development. Teratogens may also be causative, as in the case of sodium valproate and trigonocephaly. The syndromic craniosynostoses are usually genetically determined, often occurring as new mutations. There is an increasing recognition that some of the so-called isolated non-syndromic synostoses also have a genetic basis.

Genetics of craniofacial anomalies

The vast array of genetic conditions causing craniofacial anomalies precludes an exhaustive discussion of their genetics in this text. However, it is appropriate to discuss the more common conditions and encourage a low threshold for the involvement of the clinical genetics team in the management of patients with craniofacial anomalies. Clinical geneticists can contribute to both diagnosis and counselling of affected individuals and also their families. Interested readers are encouraged to consult the texts of Gorlin et al.[11] and Cohen and MacLean[4] for more extensive details on craniofacial anomaly syndromes.

When considering the aetiology of craniofacial anomalies, it is helpful to consider their aetiology in terms of **malformations** (e.g. genetic syndromes, teratogens), **deformations** (e.g. positional plagiocephaly) and **disruptions** (e.g. amniotic bands). Some craniofacial anomalies are multifactorial.

Genetic testing is not indicated in patients with isolated sagittal or metopic synostosis in whom there are no associated abnormalities or concerns about growth or development, and no significant family history. However, coronal synostosis, even when isolated, warrants analysis of at least *FGFR3* for the Pro250Arg mutation (see 'Muenke syndrome', or *FGFR3*-associated coronal synostosis syndrome below) and possibly analysis of the *TWIST* gene (see 'Saethre–Chotzen syndrome' below).

Genetic testing by DNA analysis of specific genes is available only for syndromes where the causative gene has been identified. This facilitates diagnosis and also counselling of family members, particularly when a parent may be a gene carrier with a very mild phenotype. Chromosomal analysis should be considered in any patient with complex or multiple abnormalities, or in whom there are concerns regarding a child's growth or development. Informed consent should be obtained prior to any genetic testing, especially as abnormal results may have implications for other family members as well as the child. Failure to identify a genetic abnormality in a syndromic patient does not, however, rule out a genetic cause for their condition, and involvement of a clinical geneticist is essential.

Prenatal diagnosis by genetic analysis of chorionic villus sample or amniotic fluid may be available for conditions in which the causative genetic abnormality is known. Prenatal ultrasound scanning later in pregnancy may reveal abnormal craniofacial contour or associated skeletal or systemic abnormalities in syndromic conditions; however, the premature sutural fusion of isolated craniosynostosis is much more difficult to detect.

Pathogenesis and consequences

Premature suture fusion results in inhibition of skull growth in a direction perpendicular to the affected suture. Despite this localized failure of skull growth, the brain continues to grow, and expands in different directions, where expansion can be accommodated by normal (patent) sutures, producing compensatory changes at a distance from the abnormal suture and usually parallel to it.[12] In the latter half of the last century, Moss[13] postulated that the cranial base was the site of abnormal physical stresses, and that these could be transmitted to the dura of the cranial vault, resulting in suture fusion. Whatever the underlying mechanism, the restriction of growth perpendicular to the fused suture, and the compensatory changes elsewhere in the cranium, may result in a reduction in cranial volume (and hence raised intracranial pressure (ICP)) and a change in shape (resulting in characteristic changes dependent on the suture or sutures involved) (**Table 19.2**).

TABLE 19.2 The craniosynostoses. Affected sutures and resultant head shapes. The anterior aspect of the skull (the forehead) is towards the top of the table

Shape of skull	Suture affected	Name
	Saggital	Scaphocephaly
	Metopic	Trigonocephaly
	Unilateral coronal	Frontal plagiocephaly
	Bilateral coronal	Brachycephaly
	Unilateral lambdoid	True posterior synostotic plagiocephaly

Clinical assessment and imaging

The history may be of a baby with an abnormal head shape, present at birth, gradually becoming worse. Examination reveals the characteristic head shape with ridging of the affected suture.

Plain films may allow assessment of sutural patency and the overall morphology of the skull. All sutures are usually easily visible in the normal growing skull, with the exception of the metopic suture, which normally fuses early. A prematurely fused suture may be sclerotic or may not be visible at all. The abnormal shape of the head will be apparent, and skull base abnormalities not apparent on clinical examination may be seen (e.g. the 'harlequin eye' appearance of the sphenoid ridge in coronal synostosis). Computed tomography (CT), especially when reconstituted via a 3D format, provides even more detail of the morphology of the skull (**Figure 19.1**). In addition, a CT scan allows evaluation of the intracranial contents although magnetic resonance imaging (MRI) is a more useful modality for assessing intracranial anatomy and pathology.

Raised intracranial pressure

It is logical to think of raised ICP developing as a result of failure of cranial expansion in the presence of continuing pressure from the growing brain. However, the relationship is complex, and other factors have been implicated. Raised ICP is not directly related to a decrease in intracranial volume,[14] and venous hypertension has been identified as a result of a significantly narrower jugular foramen (6.5 mm versus 11.5 mm) in complex and syndromic patients with raised ICP.[15]

The reported incidence of raised ICP in patients with craniosynostosis shows wide variation, and there is variability in the threshold for diagnosis in reported studies, with values of 15 mmHg or 20 mmHg chosen.[16] Reported incidence in mixed cohorts of non-syndromic and syndromic patients vary from 17% to 92%.[14, 17–19] Studies that have compared the incidence of raised ICP in non-syndromic and syndromic patients have shown a higher incidence in syndromic patients (approximately 50%) compared with non-syndromic patients (approximately 25%).[20, 21]

Diagnosis may be difficult because the classic clinical features of raised ICP are often absent. Thus, the child's development, in particular the acquisition of normal developmental milestones, vision, reading and language comprehension, motor skills, and general behaviour are important, and may require detailed specialist investigation, including ophthalmological assessment. Changes in visual-evoked potentials have been shown to be early indicators of raised ICP.[22, 23]

Plain skull films may show the classic 'copper-beaten' appearance of chronically raised ICP (**Figures 19.2**) but the absence of changes does not exclude raised ICP.[24] CT or MRI scanning may be helpful but, in cases where clinical assessment is equivocal, invasive ICP monitoring may be indicated, using either a traditional ICP monitor or, more recently, parenchymal fibre-optic transducers, which have been shown to be reliable as recorders of ICP and are associated with a low rate of complications.[20]

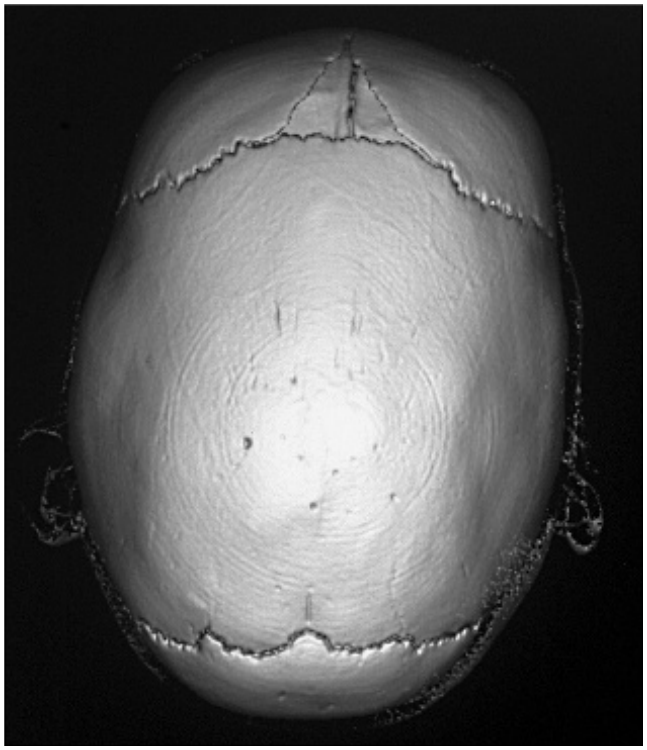

Figure 19.1 3D CT scan of patient with scaphocephaly. Note the absence of sagittal suture.

Hydrocephalus

Hydrocephalus is characterized by enlargement of the cerebral ventricles due to obstructed outflow of cerebrospinal fluid (CSF) somewhere along its path from the lateral ventricles, through the interventricular foramina, third ventricle, cerebral aqueduct, fourth ventricle and subarachnoid space to the sites of absorption. Hydrocephalus can occur in up to 20% of patients with craniosynostosis. It may be associated with chronic venous hypertension and hindbrain herniation, particularly in multisutural synostosis.

Differential diagnosis

Not all abnormal head shapes are due to craniosynostosis, and accurate diagnosis is essential since the management of non-synostotic head shape abnormalities is non-surgical. The bones of the skull in early life are relatively soft and deformable, rendering the head susceptible to alteration in shape for a variety of reasons. Non-synostotic causes of abnormal head shape include intrauterine and birth canal moulding, assisted delivery (e.g. Ventouse), intracranial abnormalities and postnatal deformational forces on the growing skull due to external pressure on the head or to uneven muscle tension in the muscles attached to the skull base.

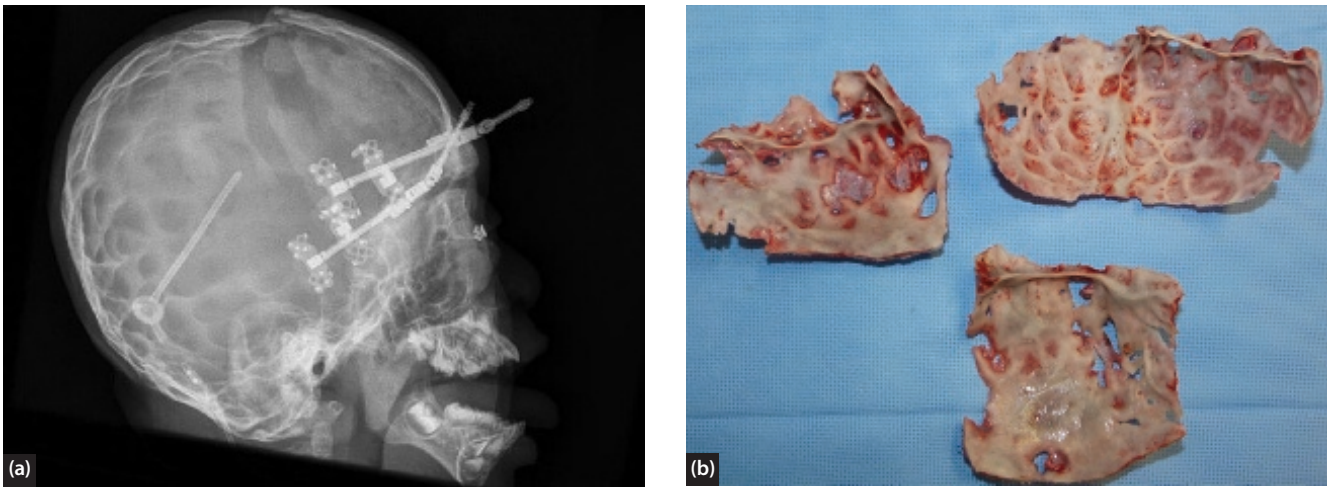

Figure 19.2 **(a)** Skull CT of a patient with raised ICP showing 'copper beating', treated with a shunt and undergoing distraction osteogenesis of the forehead. **(b)** Copper beaten bone shows indentation of underlying brain tissue.

Intrauterine, birth canal and assisted delivery moulding will be present at birth but improve fairly quickly. Intracranial abnormalities will present at birth but persist. Postnatal deformational changes are not present at birth, develop gradually and, if the cause is removed, will improve. This is in contrast to craniosynostosis, which is usually apparent at birth and progresses with growth. Diagnosis is usually possible based on the history and examination alone, but confirmation of the patency of sutures can be confirmed by plain radiographs or CT scan if needed.

The most common presentation of non-synostotic abnormalities of head shape is **occipital plagiocephaly**. This is usually due to deformational or positional plagiocephaly. The incidence of deformational plagiocephaly has significantly increased since 1992 when the National Institute of Child Health and Human Development at the US National Institutes of Health advocated and encouraged infants to sleep on their backs/supine to reduce the risk of sudden infant death syndrome (SIDS). This, combined with prematurity or potentially a delay in the ability to hold one's own head, may predispose a child to either symmetrical or asymmetrical flattening of the occiput. Other causes include abnormal head posture due to torticollis, vertebral abnormalities or ocular squint.

Clinically, there is flattening at the back of the head, often with anterior translocation of the ear on the affected side and an element of frontal bossing. Unfortunately, this condition tends to develop quickly. The natural history of this is that it tends to self-correct but may take a number of years. There is the propensity to have a mild element of asymmetry but with the combination of self-correction and increase in hair length and thickness, it is seldom noticeable. There is no surgical intervention warranted for correction of this. Orthotic firms have advocated the use of corrective helmets but the evidence to support this is currently lacking and thus the costs must be borne by the family.

General principles of surgical management of craniosynostosis

The indications for surgery are prevention and/or treatment of raised ICP, correction of significant cosmetic deformity and prevention of future skull shape deformity (or skull normalization) by allowing normal growth to take place. Essentially this allows the normalization of skull deformities and treats the raised ICP which results from a craniocerebral misproportionation.

The general principles of surgery for the craniosynostoses are to remove the cause by excising the affected suture, correct the existing deformity by reshaping the affected area of the cranium and moving it into the position it would have been in had it grown normally. This leaves an expanded intracranial volume, with a space between the dura and the repositioned bone, into which the brain can expand, thus relieving raised ICP if present. It also corrects the aesthetic deformity. Leaving a gap in the region of the excised suture, which will mimic a normal suture, should allow future growth to take place by movement of the bone in response to continued brain growth.

Timing of surgery is important. Early surgery has the advantage that ICP is normalized without delay, and the deformity may be less severe since it has had less time to develop. However, early surgery may be followed by reossification at the site of the excised suture (restenosis), with a re-emergence of the condition requiring further surgery. The timing of surgery is therefore a balance between operating too early with the risk of restenosis and operating too late when there may be prolonged raised ICP, the deformity is greater and its correction may require more extensive surgery because of lack of future brain growth and, thus, capacity for skull remodelling in response to brain growth. Another factor which must be considered is that surgery results in a significant risk of moderate, and sometimes severe, blood loss. Lastly, consideration should be given to minimizing the potential risks of undertaking a general anaesthetic on the developing brain.[25]

Major craniofacial surgery carries significant risks and complications, and a dedicated team familiar with all aspects of the management of these patients is a prerequisite for surgery to be performed. This will include a dedicated ward and theatre with appropriately trained staff, a paediatric anaesthetist and HDU/PICU facilities.

SINGLE-SUTURE NON-SYNDROMIC CRANIOSYNOSTOSIS

Most commonly, patients present with fusion (or partial fusion) of only one suture. Currently, apart from coronal synostosis, there is little evidence to state that single-suture fusion is commonly due to a Mendelian genetic change.

Sagittal synostosis (scaphocephaly)

With an incidence of approximately 1:4200–8500,[26, 27] sagittal synostosis is the most common form of craniosynostosis. Approximately 6% of cases of sagittal synostosis are familial, mostly transmitted as an autosomal dominant condition.[8] The remaining cases are sporadic and at least a proportion are likely to have multifactorial aetiology, including genetic and environmental factors. The recurrence risk to a couple with a child affected by sagittal synostosis in the absence of a family history of the condition is approximately 2%.[8]

It is usually noted at birth for its elongated skull length but the phenotypical presentation varies depending on the ensuing skull growth in the first 18 months of life. The presentation includes a relatively long, slender skull shape and often a midline sagittal ridge, corresponding to the sagittal fusion. Various or all aspects of the suture may become fused, each giving a different presentation. From a frontal perspective, the child may have significant frontal bossing, an elevated hairline and bitemporal pinching. Posteriorly, an excessive occipital bullet may develop. There may also be a middle 'saddle' deformity.

Various treatment regimes have been advocated and each unit will have their standardized technique. Depending on the age at presentation of the patient, a passive operation (including variations of strip craniectomy/microbarrel staving/spring distraction) may be performed. Older children often undergo a total calvarial vault remodelling (TVR) which addresses all the compensated growth deformities that occur. We advocate a strip craniectomy and microbarrel staving passive procedure if we are able to perform the operation safely prior to 6 months of age. If not, our patients undergo a TVR based on a modified Melbourne protocol at 12–18 months of age.[28]

Unicoronal synostosis (frontal plagiocephaly)

Unilateral/unicoronal or frontal plagiocephaly has an incidence of approximately 1 in 11 000.[4, 29] It has the most varied single-suture variation with both cranial and facial components. Cranially, this often presents with a retruded forehead and brow on the affected side, with a relative orbital dystopia (upwards on the affected side) due to the lack of anteroinferior growth secondary to the fused (or partially fused) coronal suture.

Facially, this then translates into a deviated face, expressed most significantly with a facial and nasal twist towards the affected side. There may also be a maxillary and eventually mandibular cant develop and, probably most functionally importantly, strabismus or a squint may develop. One of the aims of treatment is to obviously minimize these effects.

Bilateral coronal synostosis (brachycephaly)

Bicoronal synostosis is the most likely of all of the single-suture synostoses to have a Mendelian genetic basis.[30] Genetic testing should be offered to all patients with coronal synostosis. Testing can include the mutation hot spots in *FGFR1*, *FGFR2* and *FGFR3*, as well as full analysis of the *TWIST1* and *TCF12* genes.

Approximately 8–15% of patients with non-syndromal coronal synostosis have a family history of the condition. A positive family history is seen more often in patients with bicoronal synostosis.[7, 26] Empiric recurrence risk to a couple with a child with coronal synostosis and no family history of the condition is 5%, although genetic testing should ideally be offered in order to provide a family-specific recurrence risk.[7]

Metopic synostosis (trigonocephaly)

Traditionally thought to be the third most common form of synostosis, metopic suture fusion has over recent years seen a large increase in incidence.[31]

Between 5% and 10% of cases of metopic synostosis have been found to have a positive family history.[9] The incidence of learning disability and other developmental problems (especially expressive speech delay) is higher in patients with metopic synostosis than with other single-suture synostoses. This is at least in part due to the higher incidence of chromosomal copy number variants (CNVs) in patients with metopic synostosis. Suggestive features should therefore prompt detailed chromosomal analysis in patients with metopic synostosis, such as array comparative genomic hybridization (aCGH) studies. Environmental factors, such as exposure to teratogens during pregnancy, are a well-described cause of metopic synostosis.[32] Many cases are thought to be due to a combination of genetic and environmental factors. The empiric recurrence risk to a couple with a child with metopic synostosis with no known cause is 5%.[9]

Clinically, a wedge-shaped forehead typically ensues from premature closure of the frontal bones at the metopic suture. This prevents lateral growth of the frontal bones. This is combined with supraorbital recession and often hypotelorism, decreased interorbital and intercanthal distances. Children will often also develop wider parietal eminences due to compensated growth posterior to the fused frontal bone.

Correction of metopic (trigonocephaly) and coronal (anterior plagiocephaly/brachycephaly) is usually by means of a fronto-orbital advancement and remodelling (FOAR) (**Figure 19.3**). Individual unit protocols vary, but our institution will usually correct this from 12 to 18 months of age.

Tessier[33] originally described this procedure and it is now the mainstay for treatment of these conditions. It allows a conformational change of the forehead (and anterior cranial fossa) to take place, as well as allowing the anterior placement of the neo-forehead in order to increase the skull volume to minimize the risks of raised ICP. At the same time, the bifrontozygomatic width may be altered to correct the relative hypotelorism that ensues secondary to trigonocephaly. Conversely, this can be narrowed for patients with bicoronal synostosis.

The procedure is carried out with the patient supine. A coronal flap is raised. The forehead is then removed. This is designed by selecting bone that may subsequently facilitate a neo-forehead to be created. Techniques vary between institutions but usually this is carried out as a bilateral procedure (even for unicoronal synostosis). This then allows access to the anterior cranial fossa. The supraorbital bar is removed, protecting the frontal lobes of the brain and the eyes and optic nerves. This supraorbital bar is then corrected and remodelled to an ideal shape, allowing the neo-forehead to be attached to this. The construct is then usually replaced in an advanced position (subsequently creating an increased skull volume) and usually attached by resorbable plate fixation.

Lambdoid synostosis

Lambdoid synostosis has an incidence of only about 3% of craniosynostosis. A positive family history is rarely seen in patients with lambdoid synostosis and recurrence risks are low.[5]

The diagnosis of lambdoid synostosis is dependent on history (usually present at birth), examination (a trapezoid head shape when viewed from above compared to a parallelogram in deformational plagiocephaly, an inferiorly and posteriorly situated ear – see **Figure 19.4**) and radiologically (CT scan +/– 3D reconstruction).

Treatment of lambdoid synostosis rarely involves surgery. The risk of raised ICP is low and, once covered by hair, the negative aesthetic element of this is often minimized. If the deformity continues to cause a significant aesthetic concern or raised ICP becomes evident, a vault remodelling is usually undertaken.

SYNDROMIC CRANIOSYNOSTOSIS

It is estimated that there are over 500 different syndromes[35] that have craniofacial anomalies. From a craniosynostosis syndromic point of view, the vast majority of these patients, though, are due to the conditions outlined below. These syndromes are thought to develop through an interaction of genetic factors, molecular and cellular events, mechanical and deformations forces and secondary effects of each of these on normal growth and development.

Crouzon syndrome

Described in 1912 by a French neurosurgeon, this syndrome affects the face and cranium and occurs in 1:25 000 live births. Crouzon syndrome is characterized by craniosynostosis and maxillary hypoplasia with shallow orbits causing ocular proptosis. There is often bicoronal synostosis (brachycephaly) but occasionally the sagittal suture may also be affected. The main abnormality is an underdeveloped midface which results in prolapse of the globes ('exorbitism'), hypoplasia of the malar bones, retromaxillism and a resultant

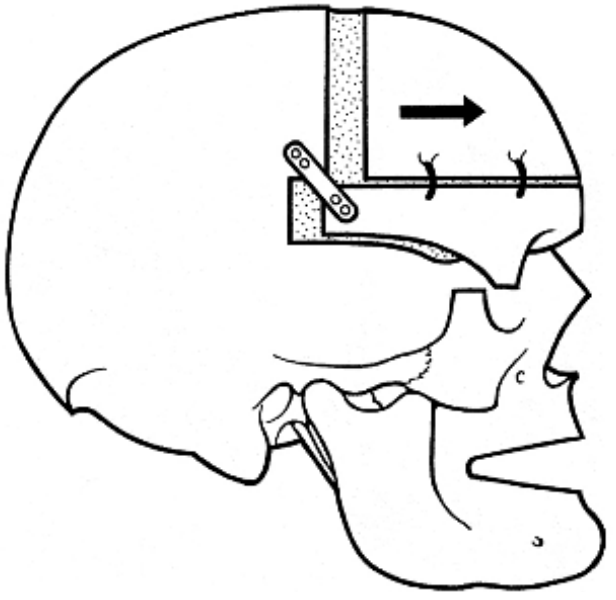

Figure 19.3 Fronto-orbital advancement surgery.

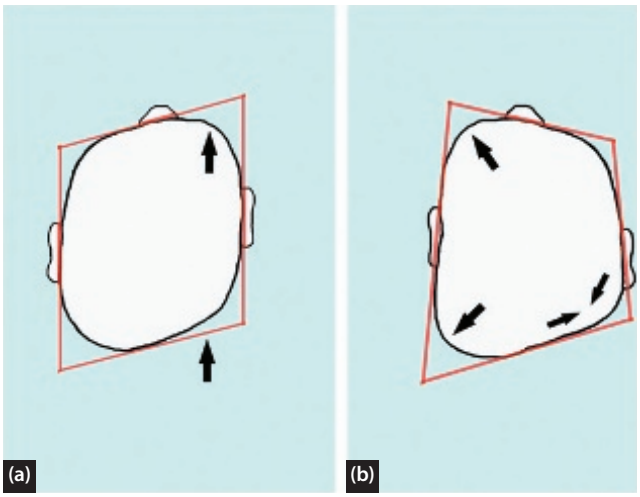

Figure 19.4 Differences between positional and true lambdoid synostosis. Positional moulding **(a)** produces a parallelogram-shaped head and the ear moves anteriorly on the affected side. Unilambdoid synostosis **(b)** produces a trapezoid-shaped head and the ear moves posteriorly towards the affected suture.

malocclusion (Figure 19.5). Anomalies of the middle ear and atresia of the external auditory canal may give rise to a conductive hearing loss. Abnormalities are usually confined to the craniofacial region although there may be systemic anomalies.[4] Intelligence is usually normal. Crouzon syndrome is caused by mutations in *FGFR2* and is autosomal dominant, although new mutations frequently arise.[29] The severity of this condition is extremely variable, even within the same family, and therefore a mildly affected parent may only be diagnosed after the birth of a more severely affected child. Severity may vary from a barely noticeable degree of proptosis and midfacial hypoplasia to, more rarely, cloverleaf skull.

Apert syndrome

Described in 1906 by Apert, this syndrome has an incidence of 1:60 000 live births. Apert syndrome is caused by mutations in *FGFR2*; two-thirds of cases have the mutation Ser252Trp while the remaining one-third have the Pro253Arg mutation.[36] There is an autosomal dominant pattern of inheritance although most cases of Apert syndrome occur without a family history as a result of new mutations and there is a link with advanced paternal age.[37] The main features of this condition include craniosynostosis (usually bicoronal), abnormal midfacial development and fusion of the digits of the hands and feet (syndactyly) (Figure 19.6). Abnormalities of the midface and cranium are evident at birth, with brachycephaly and midface retrusion causing an anterior open bite (malocclusion). Cleft soft palate or bifid uvula is present in 30% of cases. Fixation of the stapes footplate may cause a conductive hearing loss. There may be other associated malformations and intellectual ability may vary from normal to significantly impaired.[38]

Pfeiffer syndrome

First described in 1964, Pfeiffer syndrome is similar to Crouzon syndrome and is characterized by craniosynostosis and midfacial hypoplasia with shallow orbits. Additional features of Pfeiffer syndrome include broad thumbs and broad great toes. Severity of craniofacial anomalies can vary from mild midfacial hypoplasia to a cloverleaf skull (Figure 19.7). Coronal sutures are most commonly affected, with resultant brachycephaly. Other features may include skeletal anomalies such as fusion of the elbow joint, solid cartilaginous trachea and choanal stenosis or atresia. Three clinical or phenotypical subtypes have been suggested depending on the extent of associated features[4] and there is some evidence for a genotype–phenotype correlation for some mutations.[39] Pfeiffer syndrome is caused by mutations in *FGFR1* and *FGFR2*, in some cases the same mutations that can cause Crouzon syndrome.[7, 40, 41] Inheritance is autosomal dominant although many cases arise as a result of new mutations. Intelligence varies from normal to mild learning difficulties, although central nervous system abnormalities may occur in severe cases.[11]

Figure 19.5 Crouzon syndrome.

Figure 19.6 Apert syndrome. Note the brachycephaly and syndactyly.

Muenke syndrome

This autosomal dominant condition is associated with unilateral or bilateral coronal synostosis and a variety of minor anomalies. The cause is a specific mutation of *FGFR3*, the Pro250Arg mutation.[42] The phenotype this causes is extremely variable, even within the same family, and includes coronal synostosis, macrocephaly without synostosis, ptosis and minor anomalies of the hands and feet. Intelligence is usually within normal limits although learning difficulties, usually mild, may be present. The effect of the mutation may be so mild in some family members that they are unaware that they harbour a mutation. Genetic testing can be used to clarify their carrier status.

Saethre–Chotzen syndrome

Saethre–Chotzen syndrome was first described in 1931. This is an extremely variable autosomal dominant condition, although abnormalities may be milder than in other syndromic craniosynostosis conditions. Because of this, a mildly affected parent may not be aware that they also have the condition until after their more obviously affected child is diagnosed. The most commonly affected suture is the coronal suture and the craniofacial abnormalities are frequently asymmetric. Associated features may include ptosis, a low anterior hairline, small ears with a prominent horizontal crus, mild cutaneous syndactyly and broad thumbs and great toes. Mutations in the gene *TWIST1* cause Saethre–Chotzen syndrome but the phenotype has

Figure 19.7 Pfeiffer syndrome. Note the bulging temporal region, turricephaly, retruded midface and tracheostomy.

also been seen in association with the Pro250Arg mutation in *FGFR3* and with *TCF12* mutations.[43–45]

TCF12

Mutations in the *TCF12* gene are a recently identified and common cause of coronal synostosis affecting 10% of patients with unicoronal synostosis and 32% of those with bilateral synostosis, occasionally with additional sagittal involvement. Some patients have features consistent with Saethre–Chotzen syndrome, such as syndactyly, but with negative *TWIST1* analysis.[45] This is consistent with the fact that the *TCF12* and *TWIST1* proteins have been shown to interact.[45, 46] Most patients have isolated coronal synostosis with no additional features. A minority of patients with developmental delay, a learning disability or autism have been described but the majority have normal development and educational attainment.[45]

Craniofrontonasal syndrome

This condition is characterized by craniosynostosis which is usually coronal, frontonasal dysplasia, curly or frizzy hair, sloping shoulders and ridged nails. As part of the frontonasal dysplasia there is hypertelorism, a broad nasal bridge and, occasionally, a bifid nasal tip. There may also be skeletal anomalies such as joint hyperextensibilty, scoliosis and broad toes. Mutations in the gene *EFNB1* are causative.[47] The inheritance is X-linked dominant whereby females are more severely affected than males.

Carpenter syndrome

Carpenter syndrome is a very rare autosomal recessive condition characterized by craniosynostosis, which may affect all sutures causing a cloverleaf skull, and also polysyndactyly (accessory digits with fusion of the digits) and brachydactyly (shortened digits). Mixed hearing loss may also occur. Patients may have obesity and may show learning difficulties.[48] The causative gene has been identified as *RAB23*.[49]

Kleeblattschädel anomaly (cloverleaf skull)

This describes a trilobar skull and is usually caused by pansynostosis involving the coronal, lambdoid and metopic sutures, with bulging of the brain through open sagittal and sometimes squamosal sutures. The prognosis is often, but not universally, poor. Cloverleaf skull is a non-specific anomaly and may be an isolated defect or part of wider syndromes. As such, the aetiology of cloverleaf skull is varied. It may be seen in patients with certain chromosomal abnormalities or be a feature of syndromes such as Pfeiffer, Apert, Crouzon and Carpenter.

MANAGEMENT OF SYNDROMIC CRANIOSYNOSTOSIS

The aim of cranial management for syndromic craniosynostosis is similar to non-syndromic craniosynostosis. Primarily, it is to prevent or manage the raised intracranial

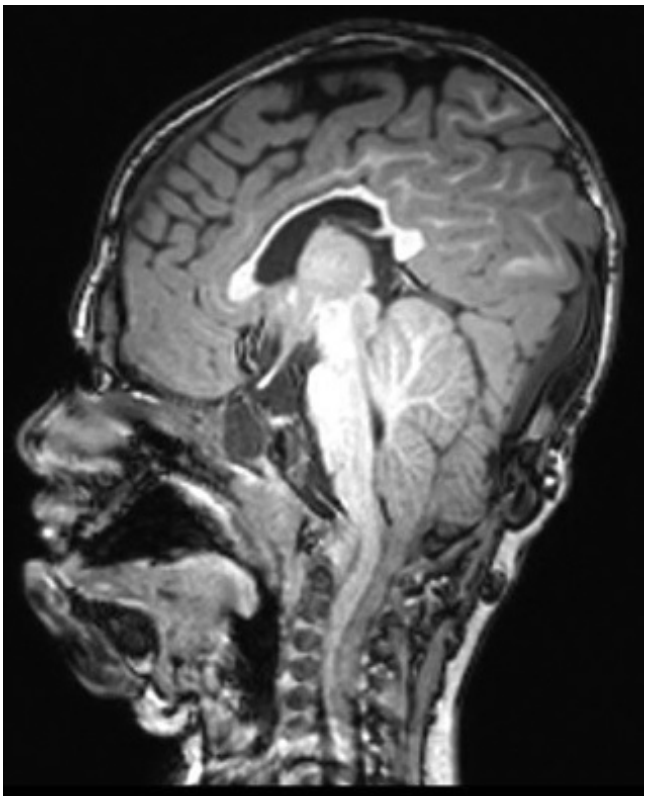

Figure 19.8 MRI scan showing a child with Crouzon syndrome with significant tonsillar herniation below the foramen magnum. Bicoronal synostosis has resulted in a significant brachycephaly deformity resulting in decreased posterior cranial fossa volume and a cramped cerebellum.

pressure that is synonymous with these conditions and to normalize the skull shape and morphology. Prior to this, though, various other factors will need to be addressed. Initially, this will include airway management, feeding and eye protection. Other comorbidities (e.g. cardiac/renal/respiratory systems) may require investigation and correction. Imaging is essential and CT brain and MRI spine and brain scans are routinely performed. In addition, support of feeding, speech and language and psychological needs is ensured by regular surveillance and input as required.

Airway

Respiratory problems may be central or peripheral. Central apnoeas may be related to a Chiari malformation and/or to raised ICP (**Figure 19.8**). An MRI must always be performed as part of a routine imaging series. More commonly, respiratory problems are secondary to obstruction, with reports of 40–83% of children being affected with obstructive sleep apnoea (OSA).[50]

Causes of obstruction in syndromic craniosynostosis are multilevel but include congenital bony nasal stenosis (CBNS) (**Figure 19.9a**), choanal atresia, nasopharyngeal narrowing, a crowded or narrow oropharynx, a thick long soft palate, subglottic stenosis, tracheal stenosis and tracheal cartilage sleeve. CBNS is caused by 3D hypoplasia of the maxilla, leading to narrowing of the nasal passages along their length. In addition, raised ICP can result in compromised neuromuscular control of airway patency.[50]

Figure 19.9 (a) CT scan showing congenital bony nasal stenosis (CBNS). **(b)** A child with Apert syndrome and CBNS managed with a nasopharyngeal airway (NPA).

CBNS and choanal atresia, particularly if bilateral, require treatment shortly after birth. Management options include dilatation with or without stenting, nasopharyngeal airways (NPAs), positive pressure ventilation using masks (non-invasive) and tracheostomy. The choice of modality is based upon a number of factors including a full airway assessment, other comorbidities geographical location, and facilities for follow-up and support and parental choice.

Dilatation and NPA insertion has been shown to be a successful first-line management option in the majority of patients (**Figure 19.9b**).[51] An NPA has the advantage over a stent of bypassing the narrow nostril but also the narrow nasopharynx and possibly the long thick soft palate. An NPA is required for 2–48 months. Carers and parents have to undergo training and demonstrate competency in managing the NPA after discharge from hospital.[52] Parents prefer management with an NPA compared to a tracheostomy.[53]

Positive pressure ventilation might be required either instead of or in addition to NPAs and other surgical interventions. Nasal continuous positive airway pressure (CPAP) using a mask has been found to be beneficial in a number of these patients, although fitting of the mask onto a retruded maxilla or a hypoplastic midface can be a challenge.

Adenotonsillar hypertrophy may contribute to ongoing obstructive symptoms and patients should be monitored for this. Although adenotonsillectomy as a treatment modality for OSA is less successful than in the general population, improvements – either symptomatic or on polysomnography (PSG) or both – are seen in up to 60% of patients. Cleft palate is a common finding in patients, particularly with Apert syndrome. A cleft palate or submucous cleft is no longer an absolute contraindication to adenoidectomy. With good visualization techniques, an inferior ridge can be left behind to enable palate–pharyngeal apposition.

Patients should be monitored both clinically and with PSG to detect severity of OSA, and early investigation and intervention is advocated. The frequency of surveillance PSG is to be determined on an individual case-by-case basis. Frequent sleep studies will often be undertaken to determine the level and severity of instruction.

Midface advancement surgery has variable effects upon upper airway obstruction. There are some reports of very successful outcomes of early midface advancement surgery in terms of decannulation or avoiding the need for a tracheostomy[54] while other reports are less positive.[55] In the authors' unit, there is generally an improvement in subjective and objective measures of OSA following midface advancement but not always sufficient to enable decannulation and/or discontinuation of CPAP.

Tracheal anomalies might also contribute towards airway obstruction in syndromic craniofacial patients. *FGFR2* syndromes such as Crouzon, Pfeiffer and Beare–Stevenson syndrome are associated with an abnormality of the trachea known as 'tracheal cartilaginous sleeve'.[56] This is a malformation in which individual tracheal arches are not formed. There is a continuous tracheal cartilaginous piece composed of a vertically fused C- or O-shaped cartilage. This might extend from the level of the subglottis down to the bronchi. When the cartilage is C-shaped, the pars membranacea is often notched posteriorly, giving the appearance of a keyhole.[57] Respiratory problems occur as a result of the reduced calibre and the reduced compliance of the trachea. Premature death occurs in almost all patients with this abnormality but a tracheostomy appears to offer a survival advantage. A tracheostomy will be more challenging to perform. Because of the rigidity of the trachea and the absence of rings, it may be necessary to cut a window rather than a vertical slit as is more common in paediatric tracheostomies. As the sleeve trachea causes narrowing, it might be necessary to select a tracheostomy tube with a smaller diameter than might be expected for age.

Post-operatively, these children are more susceptible to granulations related to trauma from suction (**Figure 19.10**). This is managed by using a shorter tracheostomy tube in order to avoid the end abutting on the abnormal ends of the C-shaped cartilage. In addition, topical application of steroids, regular attention to the 'granulomas' and education of carers with regard to suction help minimize the impact of these 'granulomas'. Nevertheless, they are a cause of significant morbidity and mortality in this group of patients.

Tracheostomy may be required either as a short-term solution, for instance to cover a surgical procedure perioperatively (e.g. midfacial advancement), or as a long-term

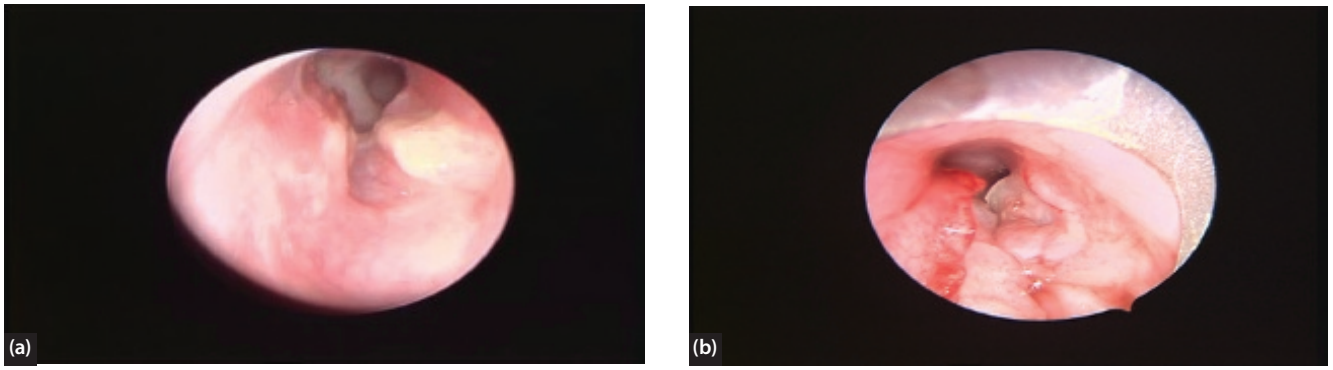

Figure 19.10 **(a)** Keyhole-shaped tracheal abnormality in Pfeiffer syndrome. **(b)** The same trachea with granulation secondary to trauma from suction. (Images courtesy of Ms M. Wyatt, Consultant Paediatric ENT surgeon, Great Ormond Street Hospital, London).

airway solution. Because the airway obstruction in these children is multilevel, a combination of approaches is required to optimize the airway. Ultimately, if these are not successful, a tracheostomy may be the safest approach.

Visual considerations

Due to both restriction of anterior frontal bone growth and midfacial hypoplasia, exorbitism (decreased orbital volume/capacity) often results. This can range from simple exorbitism with complete soft-tissue eye protection to dislocation (with or without reduction) or complete ocular exposure. Corneal abrasions are not uncommon in this situation.

Early ophthalmological assessment is imperative. Education for the family on globe reduction may be required and potentially surgical intervention (tarsorrhaphy) may be indicated.

Regular fundoscopy assessments are also mandatory to establish if raised ICP is present. Papilloedema, optic atrophy and progressive optic nerve dysfunction may accompany raised ICP. Uncorrected refractive effort, strabismus, ptosis and corneal abrasion can lead to amblyopia, potentially causing permanent visual disability if not identified and corrected.

Intracranial pressure

The mainstay of cranial surgery for syndromic craniosynostosis has been in the attempt to increase the intracranial volume, and thus control intracranial hypertension, while at the same time normalizing the head shape and thus improving the patient's overall appearance.[58] Without treatment, both visual and neurological deterioration may result. In addition to craniocerebral disproportionation, raised ICP in syndromic craniosynostosis can be influenced by venous hypertension, OSA and hydrocephalus.

As the most common cause of raised ICP is craniocerebral disproportionation, vault remodelling is intended to address this. Initially, especially for brachycephalic patients or bicoronal synostosis, a suturectomy or posterior vault expansion is advocated.[59]

Role of CSF diversion

Ventricular dilatation is a rare occurrence in non-syndromic craniosynostosis and in such cases hydrocephalus, if noted, is attributable to any coexisting disorder. However, it is a common feature of syndromic craniosynostosis and seen in nearly half the cases.[60] While non-progressive ventriculomegaly is seen commonly in Apert syndrome, it seldom requires CSF diversion. On the contrary, in Crouzon and Pfeiffer syndrome, ventriculomegaly is progressive and requires CSF diversion in most cases, despite early posterior vault expansion procedures. Patients with Saethre–Chotzen and Muenke syndrome are seldom affected by hydrocephalus.

The etiology of hydrocephalus is multifactorial: crowded posterior fossa , venous outlet obstruction and increased CSF outflow resistance are the commonest explanations.[60] The multifactorial nature of the problem is confirmed by the fact that, despite posterior vault expansion, a significant proportion of cases end up needing a shunt placement for progressive ventriculomegaly.

The options in terms of CSF diversion are limited to insertion of a ventriculoperitoneal (VP) shunt. Special precautions have to be taken to avoid shunt overdrainage as excess CSF shunting will lead to worsening of pre-existing venous hypertension (pseudotumour state). The authors recommend the use of a programmable shunt valve with inbuilt antisiphon device to obviate this problem. In the authors' experience, there is a very limited role for endoscopic third ventriculostomy (ETV) for CSF diversion. We have carried out ETV in a small number of cases with moderate ventriculomegaly post posterior vault expansion procedures in patients with subtle clinical and ophthalmological symptoms and signs of raised ICP. However, the default option for CSF diversion for hydrocephalus in syndromic craniosynostosis is insertion of a VP shunt with a programmable shunt valve with an inbuilt antisiphon device.

In our experience, the incidence of shunt infection and ventricular catheter blockage are higher in syndromic craniosynostosis, as are other shunt-related complications because of the associated problems of feeding, airway obstruction, frequent chest infections and progressive craniocerebral disproportion in these cases.

Cranial surgery for syndromic craniosynostosis

If the posterior vault size and shape is satisfactory, a fronto-orbital advancement and remodelling (FOAR) is performed[61] which both increases the volume of the skull and allows a conformational change or normalization of skull shape. Timing of this procedure varies depending on the individual institution's protocol. We will usually operate when the child is 12–18 months of age. This balances the risk of developing raised ICP if surgery is performed at a delayed stage against the risk of restenosis if the procedure is performed too early. Unfortunately, this is seldom the case and most patients will undergo a number of procedures. In our institution, depending on the severity of the craniosynostosis, a suturectomy will usually be performed. This allows continual skull growth and expansion with minimal shape deformities. This is usually only a short term measure, however, as most syndromic patients have a 'pro-ossification' genetic change and, as a consequence, the sutures will often re-fuse. Therefore, a posterior vault expansion is usually undertaken. This utilizes internal distraction devices to increase the posterior vault. It is only after the posterior vault is corrected/normalized that we address the forehead.

Midface advancement surgery for syndromic craniosynostosis

Midface advancement surgery is indicated to attempt to improve the airway in order either to avoid the need for non-invasive ventilation or a tracheostomy or to remove

dependence upon such a modality. However, outcomes of this procedure in terms of the airway are somewhat variable and unpredictable. Apart from the airway, the main indication for midface advancement surgery is to normalize appearance.

Timing of surgery to the midface is a matter of debate. In the UK, surgery is usually delayed until the age of 5–6 years, or older, prior to the child starting secondary education. This delay is intended to allow growth of the child so that their weight increases, as does the circulating blood volume. Midface surgery often results in significant loss of blood volume, with much of the haemorrhage not directly amenable to local control.

The type of surgery is dictated by the pattern of the deformity. There are three basic operations available.

1. The **Le Fort III osteotomy** involves advancement of all midfacial structures inferior to the frontal bone, i.e. nose, zygomas and maxilla en bloc. This requires a bicoronal flap for access to the nasal root, orbits and zygomatic bones and osteotomies of the nasal root, medial orbital walls, orbital floor, lateral orbital wall, frontozygomatic suture and pterygomaxillary complex. This allows mobilization of the midface. Internal fixation and bone grafts may be used to ensure satisfactory healing and stability. Due to the potential issues with achieving adequate advancement, however, this procedure is usually performed by distraction osteogenesis and a rigid external distractor (RED) frame now (see below).
2. Where midface hypoplasia is associated with hypertelorism, a **facial bipartition** may be carried out. It essentially involves a Le Fort III osteotomy to advance the midface and excision of a V-shaped segment of bone from the midline, creating two independent hemifacial segments, which can then be brought together to reduce the interorbital distance.
3. A **monobloc procedure** involves advancement of the forehead and midface at the same time by combining a Le Fort III procedure with FOAR.

See also 'Distraction osteogenesis', below.

Distraction osteogenesis

Conventional surgery involves osteotomy, mobilization and bone movement at one operation. Bone grafting and internal fixation are required to ensure healing and stability and to prevent relapse. This has the advantage of completing treatment at one operation. However, where the required bone movement is large (e.g. greater than 10 mm in the midface) or there is significant scarring of surrounding soft tissues (e.g. cleft or multiply operated patients), the desired movement may be difficult or impossible to achieve. There is also the risk of infected dead spaces (between the neoforehead and dura) in monobloc procedures due to the communication between the intracranial contents and the nasal commensal flora. The alternative of using distraction osteogenesis can be utilized to overcome these difficulties.

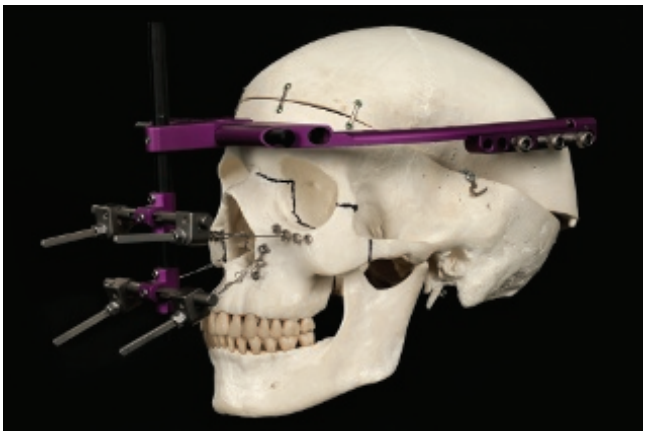

Figure 19.11 Distraction osteogenesis with a RED frame (KLS Martin RED Frame). The procedure is a craniofacial disjunction. The base of the skull is separated from the orbits/nasal bones/maxilla and underlying structures. After ensuring mobilization of these structures, titanium plates are usually secured to the nasal piriform and infraorbital region and percutaneous wires are secured to the RED frame. Progressive distraction is then commenced over the next week. The benefit of this procedure is that it allows growth of the bone as well as allowing soft-tissue expansion.

Distraction osteogenesis (DO) involves initial osteotomy, ensuring complete separation of bony segments, without mobilization or advancement, and application of an internal or external distraction device (e.g. RED frame), which is activated after a 1-week latent period and produces a movement of 1 mm per day. This allows gradual adaptation of a surrounding soft-tissue envelope, as well as osteogenesis within the osteotomy gap, allowing for greater movements without the need for bone grafting or internal fixation. Once the desired movement has been achieved, the distractors are left *in situ* for a further a period of two to three times the activation phase to allow consolidation of the newly formed bone.

Distraction therefore has the advantage of being able to produce larger movements without the requirement for bone grafts or internal fixation. The disadvantages are that the treatment is prolonged, the patient has to tolerate the distraction devices, and a second operation is often required for distractor removal. In most craniofacial patients, the advantages of distraction outweigh the disadvantages compared with conventional surgery and therefore the majority of midface advancements are now carried out using distraction (see **Figure 19.11**).

COMPLICATIONS OF CRANIOFACIAL SURGERY

Blood loss

Infants have a small absolute blood volume and there may be appreciable sudden haemorrhage, in particular from the cerebral sinuses. Blood loss varies with the timing and extent of the surgery. In a simple suture release, blood loss is in the region of 100 mL. Blood transfusion is not uncommon for

infants undergoing this surgery and for older children having more extensive procedures. Risk of viral or bacterial transmission is low but the consequences are potentially devastating. Avoiding transfusion is not always possible but, provided the intravascular volume is maintained, then patients can tolerate low haemoglobin levels.[62, 63]

The combined data of the NHS Designated Craniofacial Units reports approximately 75–85% of patients will require a blood transfusion per fronto-orbital advancement. Usually, this is due not to torrential bleeding but to the accumulation of mild ongoing losses from a prolonged procedure. Routinely, autologous blood recovery systems are used to minimize this, along with the use of relative hypotensive anaesthesia and utilization of tranexamic acid.

Air embolism

A major danger in craniofacial surgery is ingress and embolization of air through the circulation. This can occur at any stage during surgery, from inserting large-calibre central lines, raising a scalp flap or opening into the major sinuses. In anticipation of blood loss and air embolization, arterial and central venous lines are routinely used with a number of peripheral lines. A significant air embolism may result in hypotension, bradycardia and cardiac arrest. The highest risk occurs during elevation of the bone off the dura and preventative strategies are used to minimize this.

Cerebral oedema

All measures should be taken to avoid cerebral oedema. Positioning the patient correctly, ensuring correct endotracheal tube positioning and maintaining the correct intravascular fluid replacement are all vital. There should be minimal brain retraction and handling, particularly in cases of pre-existing raised ICP as this predisposes the patient to developing cerebral oedema. In many cases the use of systemic steroids (e.g. dexamethasone) may be useful in minimizing cerebral oedema.

Dural tear

Craniofacial operations such as suturectomy and vault expansion are essentially extradural procedures. In certain circumstances, for example repeat surgery or when 'copper beating' of the inner table of the skull is present, it may be impossible to avoid tears of the dura mater. The distorted anatomy must also be kept in mind and revision of pre-operative scans is imperative. Usually, small incidental tears are simply sutured closed and reinforced with fibrin glue. Larger tears may require dural grafting or formal repairs with the use of a patch.

CSF fistula

Cerebrospinal fluid leak is uncommon but will take place if a dural tear is not either recognized or adequately repaired. CSF can then leak through the scalp wound or, perhaps more commonly, leak into the nose and present as CSF rhinorrhoea. Often this is transient, lasting a few days and sealing spontaneously. Intra-operatively, it may be beneficial to perform a brief Valsalva manoeuvre in the attempt to identify any CSF (or blood) leaks. Obvious fistulae that fail to resolve must be treated. Of more concern are those that persist unnoticed and lead to infection or meningitis at a later date.

Infection

Infection can occur, particularly in cases involving communication with the paranasal sinuses, and result in meningitis, intracerebral abscess or subdural empyema. Chronic infection can also manifest as lost bone graft or implants. Post-operative infections are treated aggressively with systemic antibiotics and local debridement, with the attempt to preserve the bone flaps at all costs.

Intracerebral/subdural haematoma

Haematoma can present in the early post-operative phase with unexpected signs of raised ICP or 'lateralizing' signs.

Blindness

Surgery around the optic apex and skull base has the potential to damage the optic nerves or tracts. In particular, hypertelorism procedures and monobloc midfacial advancement carry a risk to these structures but all patients (and parents) must be informed and consented on this. Post-operative strabismus may also occur and regular ophthalmological assessments must be performed.

Restenosis

The aim of much cranial vault surgery is to release the prematurely fused sutures, thereby allowing unimpeded brain growth. The gaps created gradually ossify. Occasionally, premature restenosis takes place, and with continued brain growth there is a rise in ICP. This tends to happen more commonly in syndromic craniosynostosis than in non-syndromic cases. Saethre–Chotzen patients have a high incidence of reoperation for craniocerebral disproportionation.[64]

The potential for reossification declines with increasing age of the child (as rapid cerebral growth minimizes). In children over 1–2 years of age large bony defects of the skull vault may not close entirely. In some cases it is necessary to repair these defects using a split calvarial bone switch procedure at a later time.

HEMIFACIAL MICROSOMIA/OAVS

Gorlin et al.[65] and Beleza-Meireles et al.[66] suggested the term oculoauriculovertebral spectrum (OAVS) as a combined definition encompassing the overlapping diagnoses of hemifacial microsomia, first and second branchial arch syndrome, otomandibular dysostosis, facioauriculovertebral syndrome and Goldenhar syndrome.

TABLE 19.3 Vento's 1991 OMENS classification of oculoauriculovertebral spectrum (OAVS)

Aspect	Involvement
Orbit	
O_0	Normal orbit and position
O_1	Abnormal orbital size
O_2	Abnormal orbital position
O_3	Abnormal orbital size and position
Mandible	
M_0	Normal mandible
M_1	The mandible and glenoid fossa are small with a short ramus
M_2	The mandibular ramus is short and abnormally shaped
M_{2A}	Glenoid fossa is in anatomically acceptable position with reference to the opposite TMJ
M_{2B}	TMJ is inferiorly, medially and anteriorly displaced, with severely hypoplastic condyle
M_3	Complete absence of ramus, glenoid fossa and TMJ
Ear	
E_0	Normal ear
E_1	Mild hypoplasia and cupping with all structures present
E_2	Absence of external auditory canal with variable hypoplasia of the concha
E_3	Malpositioned lobule with absent auricle; lobular remnant usually inferiorly and anteriorly displaced
Facial nerve	
N_0	No facial nerve involvement
N_1	Upper facial nerve involvement (temporal and zygomatic branches)
N_2	Lower facial nerve involvement (buccal, mandibular and cervical branches)
N_3	All branches of the facial nerve affected. Other cranial nerves included
Soft tissue	
S_0	No obvious soft tissue or muscle deficiency
S_1	Minimal subcutaneous / muscle deficiency
S_2	Moderate – between the two extremes – S1 and S3
S_3	Severe soft tissue deficiency due to subcutaneous and muscular hypoplasia

OAVS is usually a sporadic condition. Multiple theories have been put forward to try to explain the aetiology but it is likely to be a multifactorial condition due to varying combinations of genetic and environmental (including teratogenic) factors. Rare cases (fewer than 1%) may be due to a mutation in the recently identified *MYT1* gene.[67]

Traditionally thought to have only a unilateral involvement, there is a small subset of those (around 10–25%) who are affected bilaterally. The phenotypical presentation, however, is usually different from left to right when this occurs.

Boys are three times more commonly affected than girls.[11]

Classification

Vento et al.[68] proposed the classification 'OMENS' (and OMENS-plus) to address the craniofacial aspects of OAVS (**Table 19.3**).

O – Orbit/orbitozygomatic[69]
M – Mandible – Kaban-modified,[70] Pruzansky classification[71]
E – Ear – Meurman,[72] modified Marx classification
N – Nerve (specifically facial nerve CN VII)
S – Soft tissue

Clinical diagnosis

The most striking feature of OAVS is the facial asymmetry that ensues from the involvement of the first and second branchial arches. This will usually be portrayed by a deviated chin point and subsequent dental malocclusion and/or orbital malpositioning (**Figure 19.12**).

As OAVS (or 'OMENS-plus'), has extracranial features, these should be investigated to rule out any other associated conditions. Vertebral anomalies should be looked for and investigated. A renal ultrasound and echocardiogram should also be performed to rule out renal and cardiac (e.g. tetralogy/ventricular septal defect or atrial septal defect/patent ductus arteriosus) concerns.

Orbit and orbitozygomatic involvement may vary from orbital and zygomatic malpositioning, micro- or anophthalmia, and epibulbar dermoids.

Ear deformity occurs in up to 95% of affected individuals.[73] Half of these will usually present with microtia. Associated hearing loss depends upon the development of the external auditory meatus and the middle ear. Hypoplasia of the middle ear with fusion or absence of the ossicles may occur (see Chapter 12, Congenital middle ear

Figure 19.12 Child with OAVS. Note the asymmetry and abnormal pinna.

abnormalities and Chapter 16, Microtia and external ear abnormalities).

A. N. Samadpour and H. Merrikh

Neuromuscular deficiencies involve the facial and trigeminal nerves, with hypoplasia or absence of masticatory muscles and/or muscles of facial expression. There is facial weakness in approximately 12% of patients[50] and, more rarely, other cranial nerves may be involved. Soft-tissue asymmetries are partly related to hypoplasia of the masticatory and facial muscles, but other tissues such as salivary glands may be absent.

Management

Management is aimed at addressing each individual component of the classification. This will obviously involve a MDT for the extracranial components. Treatment regimes are similar to all syndromic craniofacial patients with airway protection or establishment, eye protection and feeding as the initial priorities. Hearing assessment soon follows. After this, assessment of mandibular function and the establishment of a ramal–condyle unit will take place. Ear deformities may be corrected by prostheses or autologous reconstruction. Facial nerve procedures will vary depending on the extent of the involvement. Eventually, corrective orthognathic surgery and soft-tissue balancing procedures may be undertaken to minimize the stigmata of the condition. This may be in the patient's late teenage years. Throughout the entire treatment period, regular ophthalmological assessments are required.

TREACHER COLLINS SYNDROME (MANDIBULOFACIAL DYSOSTOSIS)

Treacher Collins syndrome (otherwise known as mandibulofacial dysostosis) is characterized by the absence or hypoplasia of the zygomatic bones, eyelid abnormalities and mandibular hypoplasia and microtia (see Chapter 16).

Aetiology

Unlike hemifacial microsomia, Treacher Collins syndrome is an autosomal dominant condition, although approximately 50% of cases have no family history and therefore represent new mutations. Its incidence is approximately 1:50 000 live births.[74] Severity is very variable and other family members may be very mildly affected. Intelligence is usually normal. Treacher Collins syndrome is caused by mutations in the gene *TCOF1*.[75]

Clinical manifestations

The palpebral fissures may be down-slanting, with colobomas of the lower eyelid and eyelash/follicle malformations being common. A hypoplastic midface with poorly developed or absent zygomas, associated with mandibular hypoplasia, results in a very characteristic facial appearance (**Figure 19.13**). The mandibular hypoplasia might be severe enough to cause significant upper airway obstruction. Features are bilateral and often symmetrical. The difficulties in both intubation and treatment that arise are due to a steep occlusal plane angle (of both the maxilla and the mandible), often dental crowding, and significant retrognthaia of the mandible. Therefore the chin point is rotated in a clockwise direction towards the larynx/trachea (**Figure 19.14**).

Bilateral ear abnormalities including hypoplasia, microtia or anotia, hypoplasia or atresia of the external auditory meatus, middle ear anomalies and associated hearing defects are common. Inner ear function is usually unaffected leading to a conductive hearing loss. There is cleft palate in 35% of cases.

Management

Management of the airway in the neonate is required to overcome respiratory obstruction associated with

Figure 19.13 Treacher Collins. Abnormalities of zygomatic bones, ears, eyelids and mandible. Note the tracheostomy.

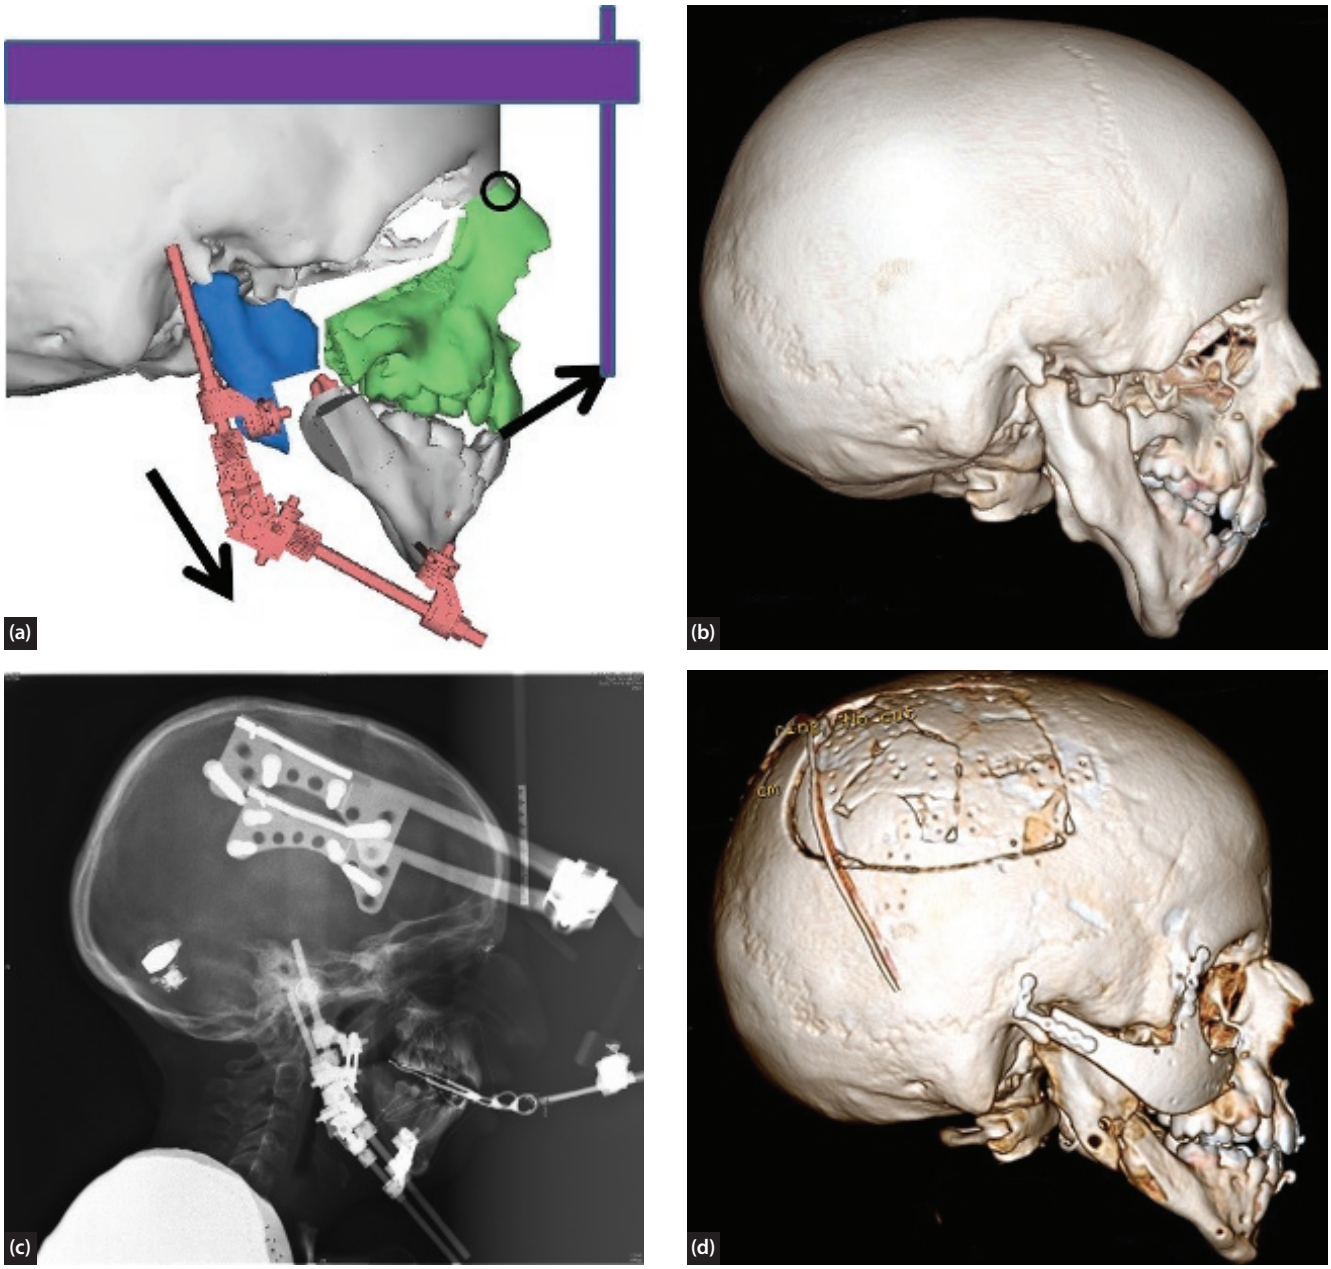

Figure 19.14 **(a)** Combination distraction osteogenesis allowing for lengthening of the mandible and rotation of the maxilla–madibular plane angle (by use of a nasion cerclage wire and traditional rigid external distraction to correct the occlusal plane). Image © Dr Richard Hopper MD. **(b)** Pre-operation. Calvarial onlay grafts used to reconstruct hypoplastic zygomatic arches. Photographs courtesy of Dr Richard Hopper MD, Seattle, Washington.

mandibular hypoplasia or choanal atresia. Early feeding difficulties may also need to be addressed. Further management may include repair of cleft palate, provision of bone-conducting hearing aid followed by a bone-anchored hearing aid, and close monitoring and intervention for speech and language development. Eyelid abnormalities may need surgical correction, hypoplastic or absent zygomas may be reconstructed, usually using calvarial bone grafts or alloplastic onlays, and mandibular deficiency can be corrected with conventional osteotomies or distraction osteogenesis (see **Figure 19.14**). Distraction techniques allow for both lengthening of the mandible in an AP direction (which addresses both the retrognathia and sometimes dental crowding) and, when combined with traditional osteotomies of the maxilla, rotation of the maxillomandibular complex in an anticlockwise direction. The latter addresses the occlusal plane and allows elevation of the chin point in a superior–anterior vector, in the hope to increase the retroglossal airway space as well as normalizing the bony skeleton and soft tissues.

ENCEPHALOMENINGOCOELE

Encephalomeningocoele represents a herniation of meninges with or without associated brain tissue, through a bony defect of the calvarium. They are a congenital anomaly representing one end of the spectrum of neural tube defects. Its diagnosis is based on the finding of either meninges and CSF (meningocoele) or nervous tissue (encephalocoele) beyond the confines of the calvarium.

The incidence of encephalocoele is reported to be as high as 1:3000 live births in South East Asia and as low as 1:10 000 live births in North America.[76]

Aetiology

Encephalocoeles may be isolated or associated with other anomalies.When other problems coexist, causes include chromosomal abnormalities, single gene disorders, teratogens and disruptions such as amniotic bands. The primary abnormality in the development of an encephalocoele is a mesodermal defect that develops when the surface ectoderm fails to separate from the neuroectoderm. This results in a defect in the calvarium and dura. Within the calvarium itself there may be failure of bone formation or pressure erosion from expanding intracranial contents. The aetiology of isolated cases is thought to be multifactorial, with both genetic and environmental factors playing a part. The widespread use of folic acid prior to conception and during pregnancy aims to reduce the frequency of neural tube defects in the general population. After the birth of an affected child, the use of high-dose folic acid prior to and after conception is recommended for subsequent pregnancies.[77]

Diagnosis

Detailed imaging is required for any nasal mass in the neonate prior to biopsy since anterior encephalocoeles may be confused with dermoids, neurofibromas and teratomas. Investigations may include an MR scan demonstrating a mass with intracranial connection and a CT scan demonstrating a bony defect in the calvarium (see **Figure 19.15** and Chapter 23, Neonatal nasal obstruction).

Classification and treatment

There are various classification systems for encephalocoele, based on the contents of the sac, site of the swelling, location of the skull defect and whether the swelling is

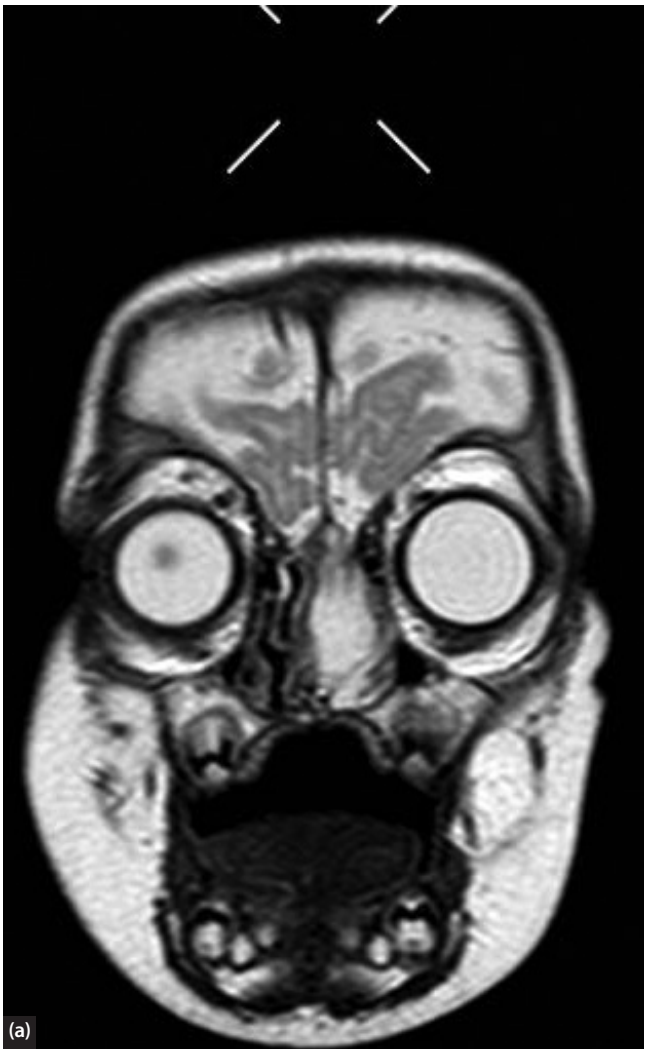

Figure 19.15 **(a)** MRI T2-weighted image of frontoethmoidal encephalocoele. Note the hypertelorism. **(b)** MRI-STIR TSE showing frontoethmoidal encephalocoele.

overt or occult. The most commonly applied system is that relating to the location of the cranial defect.

Encephalocoeles are classified as vault encephalocoeles and basal encephalocoeles based on their location in relation to vault and base of the skull. They are further subclassified as anterior (or sincipital) encephalocoeles and posterior (or occipital) encephalocoeles.

ANTERIOR ENCEPHALOCOELES

Anterior encephalocoeles have been studied extensively by Suwanwela.[78] Mahapatra further classified anterior encephaloceles[79] as follows:

A. Frontoethmoidal group
   i. Nasofrontal
   ii. Nasoethmoidal
   iii. Nasoorbital
B. Transethmoidal–nasopharyngeal
C. Transorbital
D. Transsellar–transphenoidal
E. Interfrontal (transmetiopic)
F. Anterior fontanelle

The commonest clinical presentation is swelling at the root of the nose, hypertelorism and nasal obstruction. Rare presentations are a leaking encephalocele and even with overt meningitis.

MRI of the brain and spine is the investigation of choice not only to define the lesion but also to identify associated anomalies of the entire central nervous system. Common associated anomalies are agenesis of the corpus callosum (15%), cortical dysplasia (5%) and hydrocephalus in as high as 20% of the cases.[79] CT with fine bone slices is used to define the bony defect and to better plan the bony/soft-tissue repair.

Basal encephaloceles (transethmoidal–nasopharyngeal, transphenoidal) have been at times mistaken for skull base lesions/tumours and biopsied, causing a surgical emergency in the process with CSF leak and meningitis.

Treatment

The frontoethmoidal group of encephalocoeles are managed through a bicoronal incision and craniotomy of the frontal bone and orbital bar in order to expose the neck of the encephalocoele. The neck is defined and incised to expose the contents (mainly gliotic brain). The neck is transected and repaired using dural graft. Though one-stage repair of encephalocele and correction of hypertelorism is practised by some centres around the world, our usual practice is to do a two-stage repair and defer the correction of the hypertelorism to a much later date once the upper facial growth is deemed to be complete.

The commonest post-operative complication is the development of CSF leak and hydrocephalus, which may necessitate insertion of a VP shunt in as many as 15–20% cases.

Both open and endoscopic modalities of treatment have been proposed. The recent development of endoscopic transnasal techniques has allowed the repair of these unique lesions in a minimally invasive manner as a joint neurosurgery–ENT procedure. The technique differs from the standard transcranial approach as the fundus of the encephalocoele is encountered first and the neck later. The sac of the encephalocoele sac is reduced in size with the help of cautery and the contents removed or replaced intracranial before the neck of the encepholocoele is encountered and transected. The authors' usual practice is the use of fascia lata and autologous fat to repair the skull defect and buttress the repair with a lumbar drain for a minimum of 5 days.

POSTERIOR ENCEPHALOCOELES

Vault encephalocoeles can vary greatly in size from being just a tiny skin blemish in the midline (cephalocoeles) to giant encephalocoeles. Large posterior encephalocoeles can present with difficult delivery because of their size, which can be at times giant (e.g. the size of the encephalocoele bigger than the size of the baby's head).[80]

Cephalocoele is often associated with venous anomalies such as vertical embryonic positioning of the straight sinus, splitting of the superior sagittal sinus, vein of Galen elongation, along with tenting of the tentorium.[81]

Treatment

Surgical management is primarily necessary where there is a risk of infection through communication of the lesion with the intracranial space or of rupture, or for cosmetic purposes. Surgical excision is curative in the majority of the vault encephalocoeles. Good pre-operative assessment of the venous sinus anatomy in relation to the lesion is useful in preventing serious vascular damage.

Giant encephalocoeles require semi-elective excision for fear of rupture and CSF leak and also to facilitate baby care and positioning in the cot. In the post-operative period more than 50% develop hydrocephalus and require VP shunt insertion. Associated secondary Chiari malformation and secondary sutural synostosis may require further treatment.

Prognosis

A significant percentage of the children who undergo repair of encephalocoeles will face growth, development and learning challenges and will require long-term follow-up in order to address these issues. Outcome for treated anterior encephalocoeles tends to be better than occipital encephalocoeles, with figures as low as 4 of 65 with long-term intellectual impairment.[76]

CRANIOFACIAL CLEFTS

A craniofacial cleft happens as a result of a failure of fusion of the various embryonic processes from which the craniofacial complex is formed. The exact incidence of craniofacial clefts is not known but can be estimated to be approximately 2 : 100 000 live births.[82]

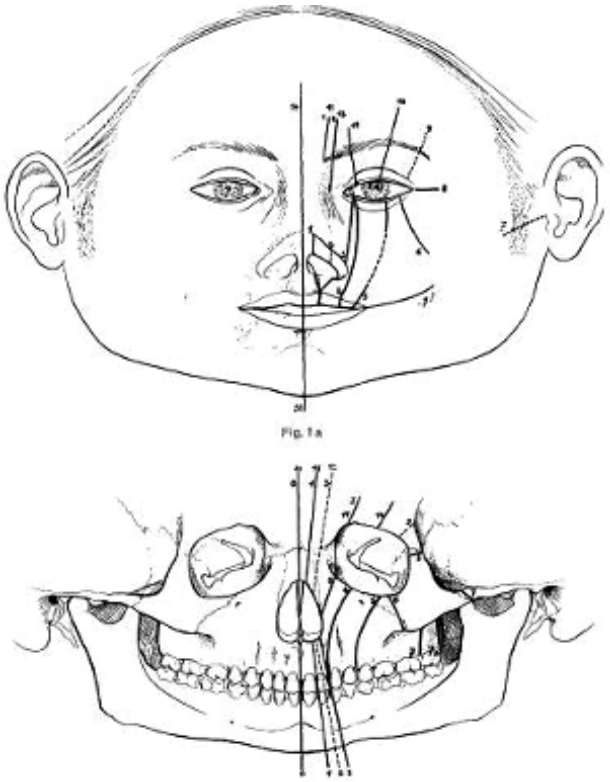

Figure 19.16 Tessier clefts. Reprinted from Tessier P. Anatomical classification of facial, craniofacial and latero-facial clefts. J Maxillofac Surg 1976; **4**: 69–92, with permission from Elsevier.[83]

Aetiology

The interplay of hereditary and environmental factors is complex and with few total cases is yet to be elucidated in detail. The majority of craniofacial clefts occur sporadically. Many factors have been implicated in the formation of craniofacial clefts, including drugs (e.g. anticonvulsants, corticosteroids and chemotherapeutic agents), radiation, infection, amniotic bands and metabolic disturbances during pregnancy. Craniofacial clefts may also be seen as part of wider syndromes such as Goldenhar syndrome.

Classification

Tessier[83] classified facial clefts according to their relationship with the orbit, nose and mouth. Numbering the clefts from 0 to 14 allowed the lower numbers to relate to the facial clefts and the higher numbers the cranial extensions (**Figure 19.16**) (see Chapter 18, Cleft lip and palate).

Clinical features

The clinical features are variable depending on the type of cleft. Clefts affecting the interorbital area result in hypertelorism and orbital dystopia (see **Figure 19.17**).

Figure 19.17 Facial cleft. Pre-operative **(a)** and post-operative **(b)** views.

Management

Surgical treatment will depend upon the site, size and severity of the cleft. The extent of the cleft can be variable, ranging from a notch in the soft tissues or soft-tissue deficiency to a severe cleft affecting skin, bone and brain.

Treatment will usually involve reconstitution of the layers, replacement of missing anatomical structures and normalization of secondary distortions.

FUTURE RESEARCH

- Technological advances have allowed the implementation of endoscopic instruments in the attempt to perform a relatively smaller craniofacial operation. The most common situation is currently to perform an endoscopic strip craniectomy for scaphocephaly combined with helmet therapy to achieve the desired morphological head shape change. Advocates of this technology and these techniques state that there is a smaller incision and also less blood loss intra-operatively. The converse argument, however, is that, if there is an intra-operative complication such as massive blood loss or dural tears/air emboli, surgical access is limited and significant blood is lost prior to being able to control it.
- Spring-assisted cranioplasty has been utilized in a number of conditions. Originally introduced by Lauritzen,[34] the procedure involves inserting an omega-shaped spring, made of stainless steel wire, usually after a osteotomy has been performed. The spring is then inserted and a constant force is applied across the osteotomy site. This technique shows great promise and has a proven track record from a safety point of view. Some criticism, though, has been received from not being able to modify the direction of expansion, sometimes a compromised aesthetic outcome and they require a second procedure to remove them.
- Mandibular distraction in children with mandibular hypoplasia to improve airway. Classically, this has been utilized in Pierre Robin sequence in an attempt to improve airway obstruction and prevent the need for tracheostomy, but there is growing evidence to suggest that most forms of significant mandibular retrognathia will benefit from distraction osteogenesis.[84] The procedure can be repeated in severe cases.
- High-resolution 3D imaging has allowed for the introduction of computer-assisted surgery. Detailed scans are imported into a proprietary program which allows manipulation of the 'bones'. Pre-surgery osteotomy cuts can be simulated by the computer, predicting the outcome of the operation. This then allows cutting guides to be fabricated intra-operatively and patient-specific plates to created. The significant benefits of this include an increase in speed of the operation and a predictable outcome that is visualized prior to surgery.

KEY POINTS

- Craniofacial surgery is undertaken in designated centres, with access to MDTs and critical care facilities.
- Children with syndromic craniosynostosis have a high incidence of airway problems, including OSA.
- Some children with severe craniofacial disorders will need long-term tracheostomy.
- Children likely to develop OSA should be monitored both clinically and with PSG to detect severity of OSA and to plan early investigation and intervention.
- Microtia is an important feature of many craniofacial disorders, particularly OAVS/hemifacial macrosomia and Treacher Collins syndrome
- Detailed imaging is essential for any nasal mass in the neonate prior to biopsy.
- Families of children with craniofacial disorders should be offered a consultation with a clinical geneticist.

CHAPTER 20

BALANCE DISORDERS IN CHILDREN

Louisa Murdin and Gavin A.J. Morrison

SEARCH STRATEGY

A number of search strategies were employed for this chapter. Using dizziness, vertigo, paediatric/pediatric/child and the major conditions as keywords, the following databases were consulted: Embase, Ovid Medline (R) and Journals @ Ovid full text subset.

INTRODUCTION

Young children do not usually complain of vertigo; history and diagnosis can be elusive. Owing to this, the pattern of symptoms in the very young has a wide differential diagnosis. Once middle ear disease and congenital or hereditary sensorineural conditions have been excluded, a large percentage will have dizziness associated with migraine. Posterior fossa neurological disease should be considered; in older children, adult causes of vertigo may be seen. Reassurance that the prognosis is favourable, and antihistamines such as cinnarizine or, if appropriate, antimigraine treatments are usually effective.

Estimates of prevalence of vestibular disorders in children suggest that the experience of vertigo is not especially rare. In one community-based study of children aged 1 to 15 years, 8% had experienced vertigo and in 23% of these it was severe enough that it interfered with activity.[1]

MATURATION OF THE VESTIBULAR SYSTEM

The otic capsule develops early in gestation between the fourth and twelfth weeks of intrauterine life. As the vestibular system is phylogenetically older than its auditory counterpart, each stage in development is in advance of the auditory system and therefore less vulnerable to environmental insult. The semicircular canals have formed from the utricular portion of the otic vesicle by the 30 mm stage, while the cochlear duct has two and a half coils by the 50 mm stage.[2] The vestibular nerve myelinates by 16 weeks *in utero*. By 24 weeks there is even a primitive vestibulo-ocular reflex present.

After birth, at 4 months of age, the baby can tilt its head to keep it vertical. It is the first sensory system to develop. Vestibular function is present at birth. Full-term babies demonstrate a 'doll's eye response'. When the baby is rotated, eye and head deviation is seen in the direction opposite to the direction of rotation. This is akin to the nystagmus seen in adults on rotation, but without the saccadic fast phases that have not yet matured at this age. Maturation of the vestibulospinal and vestibulo-ocular reflexes continues so that responses are maximal at 6–12 months of age.

Beyond this, responses decline, as part of normal motor development, to reach adult values around 10–14 years of age. Bithermal caloric responses can be made in 9-month-old babies if necessary, to measure the vestibulo-ocular reflex. Vestibular nystagmus in children, however, tends to be of a lower frequency and greater amplitude. Maximum slow-phase velocity readings are often similar to those in adults, but the normal ranges for the canal paresis and directional preponderance calculations are wider than those seen in adults.

Infantile reflex responses and motor milestones

The Moro response comprises a sudden bilateral extension of the upper limbs evoked by sudden jarring of the cot or dropping the head backwards by a few centimetres. This response is present in normal children at birth, and disappears by the sixth month. The secondary inherent responses are righting responses and protective reactions. From 4 months, the infant will tilt the head to maintain it vertical if the trunk is tilted laterally through 30° (head-righting reflex). The ages of sitting unsupported, crawling and walking bear some relation to vestibular function but also depend upon neurodevelopment. Vision also plays an important part in postural control.

ASSESSMENT OF THE DIZZY CHILD

Symptoms of vertigo in children

Childhood vertigo results from a mismatch of information from the three different sensory systems: vestibular, visual and proprioceptive. Vertigo, however, is much more difficult to recognize in babies and children than in adults; younger children are not able to describe what they are experiencing and may present with other behavioural symptoms. Parents or carers may report seeing the child suddenly cry out and drop to the floor or cling to the legs of adults, pallor, sweating, vomiting, screaming, lying face down in the cot and showing reluctance to be moved.[3] Interestingly, children born with a congenital lack of normal vestibular function often have no balance disturbance at all although they may have mildly delayed motor milestones. Vision remains by far the most important sense for locomotor and balance acquisition.

It is helpful to direct the history taking with a number of principal and most likely diagnoses in mind. In the paediatric age group the principal conditions to consider are:

- benign paroxysmal vertigo of childhood
- migraine associated vertigo
- epilepsy
- central causes of ataxia and loss of balance
- vestibular neuronitis
- BPPV
- adult causes, e.g. Menière's disease.

A more complete list is given in **Box 20.1**.

The presentation of vertigo varies quite dramatically according to the age of the child. While it is possible for 2-year-olds to experience acute vertigo, young children cannot describe this and may even present with torticollis. If there is a delay in motor milestones, children may present with poor balance or falling; this can also be associated with simple conditions such as 'glue ear'. By 5 years of age, short-lived dizzy episodes can be described, the common cause being benign paroxysmal vertigo (BPV) of childhood. By the teenage years, migrainous vertigo, psychogenic vertigo and the adult vertiginous conditions are much more common.

BOX 20.1 Causes of childhood vestibular symptoms

Conditions with hearing loss	Conditions with normal hearing
OME	Motion sickness
Suppurative ear disease	BPV of childhood
Cholesteatoma with fistula	Basilar migraine
Temporal bone trauma	Seizure disorders
Barotraumatic perilymph fistula	BPPV
Menière's disease	Post-traumatic vertigo
Post-traumatic vertigo	Viral labyrinthitis or neuronitis
Enlarged vestibular aqueduct syndrome	Posterior fossa tumours
Other congenital temporal bone anomalies, e.g. CHARGE association	Cardiac causes: syncope and arrhythmias
Dehiscent superior semicircular canal syndrome	Acute poisoning
Drug-induced ototoxicity	Multiple sclerosis and Lyme disease
Congenital syphilis	CNS infections: Coxsackie A and B, echovirus encephalitis or HIV infection
Herpes zoster oticus	Meningitis: viral or bacterial
Congenital CMV infection	Chiari malformations
Metabolic conditions: Hurler syndrome, hypothyroidism	Hereditary cerebellar ataxias
Usher syndrome	Acute cerebellar ataxia

History taking

It is helpful to establish the nature of the dizziness, whether it is true vertigo, loss of balance or a light-headed faint feeling. The duration and periodicity can be useful guides, as may precipitating factors such as head or neck injury.

The presence of frequent headaches and whether they occur with vertigo or at other times is important. Associated vomiting may be an indication of an acute true vertigo, a migraine phenomenon or the presence of raised intracranial pressure. Associated hearing loss, otalgia or otorrhoea are important. It can be helpful to categorize childhood dizziness into conditions with normal hearing and those with associated deafness (see **Box 20.1**).

A neurological history is essential, specifically if there is anything to suggest temporal lobe seizures, visual or olfactory hallucinations. The developmental history, in terms of the motor milestones, or any regression should be ascertained. The presence of a recent pyrexial illness, the drug history both current, past and, indeed, *in utero* can be important, and various sorts of poisoning should be borne in mind in the child who becomes acutely ill with vertigo and may have ingested something while playing. In the ill, febrile child a range of serious infectious diseases should be considered. In a slightly older child, it may

be more apparent that the problem is one of fainting or hyperventilation, or that there are cyanotic attacks or palpitations in association with the dizziness.

The family history is relevant, especially one of maternal migraine, familial sensorineural deafness or neurofibromatosis type 2 (NF2).

Examination of the dizzy child

Much of the paediatric vestibular examination can be carried out through observation of the child from the waiting area, moving into the consulting room. The routine paediatric examination will include otoscopy. Facial nerve function, tongue movements and the gag reflex should be checked. It is important to look at eye movements. This should include a cover test to check for strabismus and latent nystagmus, and, in particular, to search for nystagmus both with and without visual fixation. Head-shaking nystagmus can also be used effectively in children to unmask a unilateral peripheral vestibular deficit. Smooth pursuit, saccades and optokinetic nystagmus can be elicited using visually attractive targets. The standard clinical balance assessments can be undertaken, such as Romberg's test, Untenberger's stepping test and the tandem heel–toe gait. It is helpful to make this fun for the child by introducing games, such as hopping and kicking a football, to assess balance function better. Head thrust testing can be helpful in diagnosing a unilateral peripheral deficit. Dix-Hallpike positional testing should also be undertaken (see Chapter 62, Evaluation of balance).

Neurological examination of the limbs should be undertaken to seek signs of spasticity, myopathy, sensory neuropathy or other causes of gait abnormality. Rotation testing is easily carried out on an office chair with the child on the parent's lap. Cerebellar ataxia is seen on heel-toe tandem gait with dysmetria, but with normal ranges of lower limb motion and unchanged gait velocity and stride length. Characteristically, gait is wide based with dys-synergia and dysrhythmia, and balance is poor.[4]

Investigations

Audiometry is mandatory. This should comprise a pure tone audiogram or alternative threshold assessment, such as visual reinforcement audiometry, if the child's age or development demands it. Objective testing with brainstem auditory-evoked responses may be indicated. Tympanometry should also be undertaken.

Routine blood tests to exclude anaemia or other blood dyscrasias are worthwhile. The white cell count and inflammatory markers (erythrocyte sedimentation rate – ESR- or C-reactive protein) may give a clue to an infective condition which could have led, for example, to cerebellar encephalitis. Serology should exclude congenital syphilis, and human immunodeficiency virus (HIV) disease might be considered.

Depending on the history and the level of concern, other investigations might include formal rotation testing, bithermal caloric testing with videonystagmography or electronystagmography recordings. Vestibular evoked myogenic potentials (VEMPs) have also been successfully recorded in children and babies.[5] Ocular VEMPs are also suitable to record in children over 2.[6]

Imaging the head and inner ears with magnetic resonance (MR) scanning and/or a high-resolution computed tomography (CT) scan for the bony labyrinth and temporal bones will be indicated in selected children. For example, reassurance that there is no space-occupying lesion in a child with headaches and vertebrobasilar migraine, or defining an enlarged vestibular aqueduct in association with sensorineural hearing loss could be important. If the diagnosis is clinically obvious, however, it is unnecessary to undertake brain scanning.

Where the history indicates it, referral for an electroencephalogram (EEG) and neurological opinion or for an electrocardiogram and cardiac review may have to be considered.

CAUSES OF CHILDHOOD VESTIBULAR SYMPTOMS

The diagnostic flow chart (**Figure 20.1**) summarizes the diagnostic process in managing the child with vestibular symptoms. The conditions are discussed in more detail below.

VESTIBULAR CONDITIONS WITH NORMAL HEARING

Box 20.1 lists most of the conditions that can present with childhood vertigo, dizziness or balance problems. Although the differential diagnosis is extensive, in over half the children who present to the paediatric otolaryngologist with dizziness or disequilibrium, the cause will be otitis media with effusion (OME or 'glue ear'), BPV of childhood or dizziness as a migraine phenomenon.[7] A further study indicates the most common causes for vertigo in children to be migraine in 31% and BPV of childhood in 25%.[8] Other less frequent causes include trauma with deafness, delayed endolymphatic hydrops, benign positional vertigo and, more rarely, cerebellopontine angle tumour, seizures, acute vestibular neuritis or juvenile rheumatoid arthritis. In this study, abnormalities were found in hearing in 24%, in positional testing in 5%, in 11% of bithermal caloric tests, and in 65% on rotational chair testing.[8]

Motion sickness

Motion sickness is caused by a conflict in the kinetic input, often with an excessive vestibular stimulation. Girls are more commonly affected than boys and it tends to settle at puberty. Interestingly, motion sickness can occur in people with blindness, but can also be caused by purely visual stimulation. There is an association with migraine and vestibular dysfunction.[9]

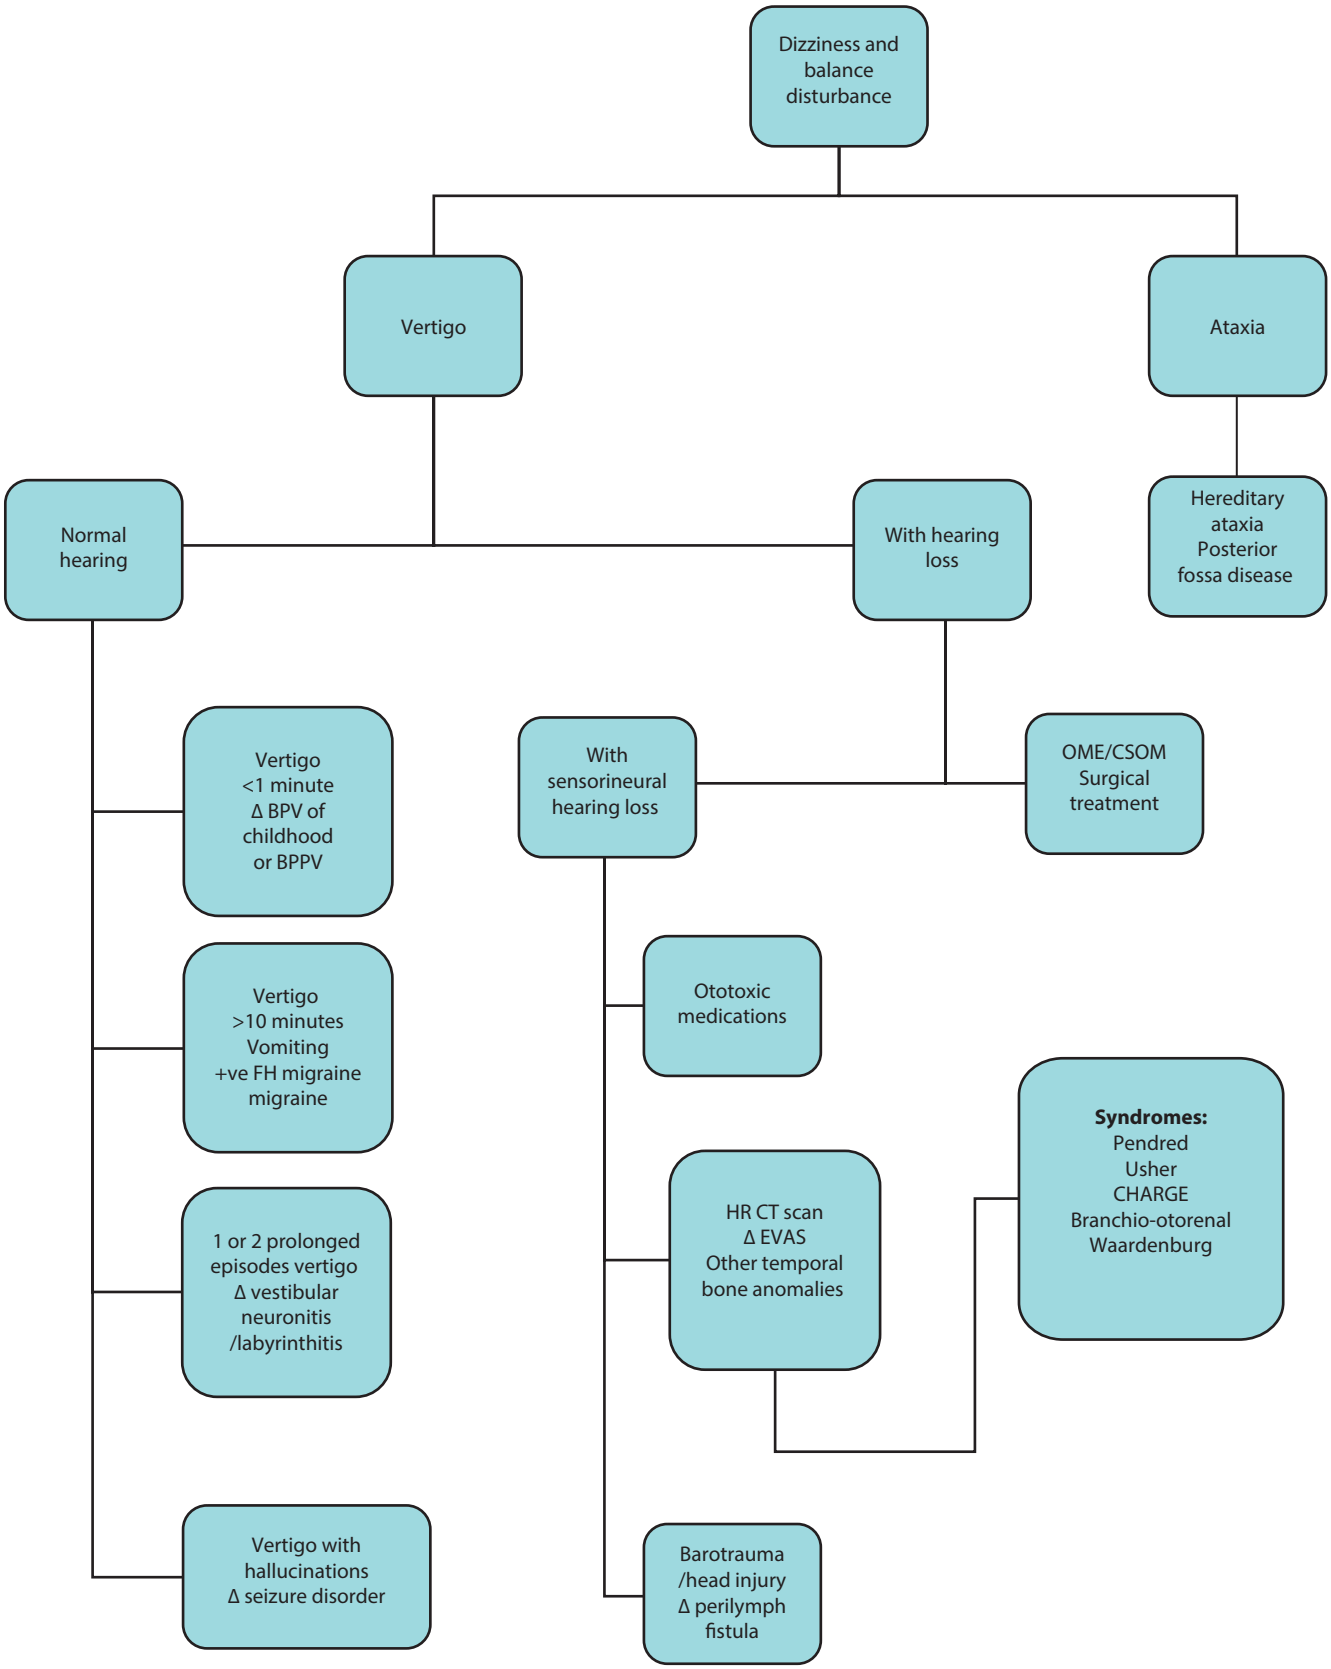

Figure 20.1 Diagnostic flow chart for balance disturbances in children.

Benign paroxysmal vertigo of childhood

Benign paroxysmal vertigo of childhood is not a positional vertigo and is quite different from benign paroxysmal positional vertigo (BPPV). It occurs in children who are aged 4 or over, with no obvious precipitating factors. It is a very frequent cause of paediatric dizziness, being found in 35% of children with dizziness in one series.[10] The child experiences short-lived acute vertigo for 30–60 seconds. He or she may fall or hold onto something suddenly and cry, becoming anxious, pale and sweaty and frequently vomiting. There is then a rapid return to complete normality a few minutes later. Nystagmus is present during attacks which are recurrent and variable in frequency, but interictal neurological examination is normal.[11] Attacks can continue in older children but usually subside. Half of these children go on to develop migraine in adolescence. Most have a family history of migraine. Caloric abnormalities are quite likely to be present if recordings are made.

A related condition that presents in a slightly younger age group is benign paroxysmal torticollis. Torticollis is not related to vertigo, however. There is a suggestion that creatinine kinase levels are likely to be elevated in BPV of childhood, and measurement may be helpful in diagnosis.[12]

BPV has a very favourable long-term prognosis. In one study the condition had resolved by about 8 years of age, and on long-term follow-up 21% had developed migraine but none had any vertigo or balance disorder.[13] The differential diagnosis of a child or baby presenting with marked torticollis is large and varied and should include congenital torticollis, paroxysmal torticollis with vertigo, mastoiditis or neck abscess, skull base tumour and neurological extrapyramidal spasmodic torticollis or psychogenic spasmodic torticollis.

Migraine and vertigo

Migraine is a common multifactorial neurovascular disorder. Several mutations have been discovered for rare forms of migraine; one within *CACNA1A* on chromosome 19p13, a gene encoding for part of a neuronal calcium channel codes mutations for familial hemiplegic migraine type 1 and also in episodic ataxia type 2. Genome-wide association studies have been carried out for more common forms of migraine; however, these are genetically complex with many different contributory genetic variations.

The prevalence of migraine in children and adolescents over periods between 6 months and lifetime is 7.7% (95% CI 7.6–7.8). Migraine presents differently in children when compared to adults, with shorter headaches that are more likely to be bilateral.[11] Vestibular migraine is a subtype of migraine present in the Appendix of the most recent International Classification of Headache Disorders (ICHD) classification. Basilar-type migraine is diagnosed when other symptoms attributable to the posterior circulation are present and ascribed to aura phenomena. Migraine is identified as a primary diagnosis in around 25% of those children presenting with dizziness. Headache need not be present with all attacks of dizziness. In one study into migraine-related vestibulopathy, common vestibular test abnormalities included a directional preponderance on rotational testing, unilateral reduced caloric responsiveness and vestibular system dysfunction patterns on posturography.

If dietary triggers are identifiable, they can be avoided, but there is no evidence that cutting out foods such as cheese or chocolate reduces frequency of migraine, and restricting children's diets is unlikely to be productive; in some cases it has been the cause of malnutrition.[14] Fasting, by contrast, is a proven trigger so encouraging regular meals and snacks is prudent. If attacks are occurring more than once a week, prophylaxis and prescribing prophylactic antimigraine medications may be considered as an option. Symptomatic relief has also been provided using anti-motion sickness medications, vestibular rehabilitation and pharmacotherapy directed at any associated anxiety.[15] Associated headache can be treated acutely in children over 12 years old with triptans.[16] Some more recent evidence supports selected use in 6–12-year-olds.[14] Electroencephalographic changes are seen during and shortly after a migraine attack but fully resolve in time. EEG, carried out within 4 hours of the onset of symptoms (initial stage), shows a diffuse polymorphic subdelta–delta activity. EEG, performed 16 hours after the onset of symptoms, shows delta–theta activity predominant over the occipital regions.[17]

Videonystagmography studies in children with migraine, undertaken during spontaneous nystagmus, gaze nystagmus, eye-tracking test, optokinetic and positional nystagmus and caloric testing, showed that all patients with migraine had abnormalities in vestibular testing. Analysis of the results suggested a mainly central localization of vestibular dysfunction.[18]

Vestibular neuronitis

Vestibular neuronitis presents as it does in adults, with acute severe vertigo, nausea and often vomiting but normal hearing. Characteristic nystagmus is seen during acute attacks. Children recover more quickly from this disorder than do adults. Half of patients can have repeated episodes, although within a few years attacks become progressively less severe and are likely to cease. Treatment is with vestibular rehabilitation, which in children takes the form of games (ball games, picking up of toys on the floor, and rapid head movements with gaze fixation on fixed targets).[19]

Benign paroxysmal positional vertigo

While in adults BPPV most commonly occurs spontaneously or follows vestibular neuronitis sometime previously, in children it is rare and BPPV is more likely to occur following a head injury or marked whiplash injury. The characteristic nystagmus seen in adults has been documented in children.[20] It has a good prognosis. In one study on children's temporal bones in Boston, 12.7% of paediatric temporal bones examined had basophilic deposits, many of them with otoconial crystals in the semicircular canals. That is much higher than the incidence in children

who had any vertigo symptoms, a temporal bone finding mirrored for this condition in adults.[21] The exact pathogenesis of BPPV is not yet fully explained.

Post-traumatic vertigo

The complaint of dizziness and headaches quite commonly follows head injury in children. The relatively high incidence of these persistent post-traumatic symptoms in children and adolescents presents a diagnostic challenge. It is often difficult to differentiate between functional complaints generated by psychological trauma or compensation seeking and an organic aetiology.[22]

Seizure disorders

Recurrent unprovoked seizures due to epilepsy are either generalized or localized (focal). Seizure disorders can give rise to vertigo in two ways: first, in the aura of a generalized (grand mal) fit; second, as vertiginous epilepsy or vestibulogenic epilepsy. In temporal lobe or occipital lobe focal epilepsy there may be transient loss of consciousness or amnesia; the child may describe the sensation of movement and may have visual or auditory hallucinations. There may be motor or emotional components. Convulsive epilepsies are generally unmistakable. Absence epilepsies may be recognized by the provocation of an episode during hyperventilation. Complex partial seizures in children can be difficult to distinguish from behavioural problems, shuddering attacks, paroxysmal vertigo, breath-holding spells, cardiogenic syncope, night terrors and movement disorders, such as paroxysmal kinesigenic choreoathetosis.[23]

A comparison of the elementary visual hallucinations of 50 patients with migraine and 20 patients with occipital epileptic seizures showed that in epileptic seizures they are predominantly multicoloured with circular or spherical patterns as opposed to the predominantly black and white linear patterns of migraine. This simple clinical symptom of elementary visual hallucinations may be helpful in distinguishing between classic or basilar migraine and visual partial epileptic seizures, particularly in children.[24] Referral to paediatric neurology is required if vertiginous epilepsy is suspected.

Psychogenic (conversion reaction) vertigo

Psychogenic dizziness should be diagnosed after excluding organic pathology. Sometimes seen in adolescents, more commonly girls, it is said to occur in children who are put under parental pressure to achieve. Recurrent fainting episodes can be seen in adolescence, when the possibility of a cardiac cause should be considered. In surdocardiac syndrome, for example, there is a prolonged QT interval, fainting and a risk of sudden death.

Psychogenic vertigo as a conversion reaction can be seen alone or in association with psychogenic hearing loss. The discrepancy between symptoms and findings in audiometric or vestibular tests is the essential clue for reaching a diagnosis of a conversion disorder. Referral to a psychiatrist may be necessary because many patients have problems in school or at home, and recovery may take a long time.[25]

Miscellaneous conditions with normal hearing

There are a number of other conditions which can mimic vertigo that are worth considering in the infant or child with unusual symptoms. These include toddler breath-holding attacks.

POISONING

In a child with dizziness, nausea and vertigo, among other symptoms, acute poisoning from plants, chemicals or drugs should be considered.

ATAXIA

Ataxia and other primarily neurological, hereditary or degenerative conditions are rare. They are discussed in a separate section (see 'Persistent imbalance and ataxia: central disorders' below).

VESTIBULAR CONDITIONS WITH ASSOCIATED HEARING LOSS

Otitis media with effusion and chronic suppurative ear disease

Glue ear may be detected in the clumsy child with poor balance who is more prone to falls than his siblings or peers. Chronic suppurative otitis media (CSOM) with perforation and infections can influence general balance and CSOM with cholesteatoma carries the possibility of a fistula to the lateral semicircular canal or oval window accounting for dizziness or leading to suppurative labyrinthitis.

Menière's disease

Childhood or adolescent onset of Menière's disease, although uncommon, is well documented. In one series, sporadic Menière's disease began in childhood in less than 3%, although, in the less common familial Menière's disease in more than 9%, no doubt due to the phenomenon of anticipation. The clinical features are indistinguishable from those in adults; however, early onset tends to be associated with more aggressive disease and a likelihood of relatively early bilateral involvement.[26, 27]

Associated temporal bone abnormalities and hearing loss

In numerous conditions and syndromes there is sensorineural hearing loss with temporal bone anomalies. In only a small number of these conditions are children likely

to present with vestibular symptoms. Vision remains the most important special sense in acquiring balance. Children with bilateral vestibular impairment may be delayed somewhat in motor development but rarely present with vertigo. Not surprisingly, in conditions where there is abnormal or absent vestibular development and visual loss, children are more likely to present with balance disturbances. Children with Usher syndrome have vestibular hypofunction and may therefore have balance difficulties when vision is also impaired.

In CHARGE association (see Chapter 23, Neonatal nasal obstruction) there are frequently abnormalities, for example a primitive otocyst, and such children may have absent semicircular canals and an aberrant facial nerve. A study from Ann Arbor researched patients with severe sensorineural hearing loss and agenesis of the semicircular canals. Most had CHARGE syndrome, some were non-syndromic, and one had Noonan syndrome. They did not present with vertigo.[27] X-linked hereditary deafness is another example in which vestibular symptoms are uncommon despite vestibular hypofunction. Vestibular hypofunction may be present in Down syndrome.

Enlarged vestibular aqueduct syndrome

Enlarged vestibular aqueduct syndrome is a rare congenital anomaly; vestibular disturbance is uncommon but is seen in 4% of children. Fluctuant and progressive sensorineural hearing loss is the norm and is bilateral in 87% of cases. A vestibular aqueduct radiologically wider than 1.5 mm at its midpoint or wider than 2 mm at the operculum is defined as enlarged.[28] Most patients maintain stable hearing in at least one ear over a 4-year period. It can occur in non-syndromic conditions but is also found in 50% of patients with Waardenburg syndrome (types 1 and 2), in which there may be significant widening of the vestibular aqueduct at its midpoint together with other temporal bone anomalies.[29] These children tend to have profound or severe hearing loss. Up to 30% of children with Waardenburg syndrome have vestibular impairment and some experience episodic vertigo. Enlarged vestibular aqueduct syndrome is also seen in Pendred and the branchio-otorenal syndromes, often with an associated Mondini deformity in the former. Patients with enlarged vestibular aqueduct syndrome may show an autosomal recessive inheritance (see Chapter 10, Management of the hearing impaired child).[30]

Avoidance of head injuries is recommended but this may not influence the progression of deafness. The pathogenesis is ill-understood. Surgery to occlude the vestibular aqueduct remains controversial. Conservative management is advised.

The patent cochlear aqueduct

The cochlear aqueduct at its narrowest portion is 0.14 mm wide. It widens as it opens into the posterior fossa with a very variable size at this point. The late Peter Phelps, who had extensive experience in the histopathology of temporal bones, stated that his study of 1400 normal temporal bones and 29 with dysmorphic labyrinths had failed to show a dilated cochlear aqueduct, and he believed that sensorineural deafness attributed to this, in fact, related to defects at the fundus of the internal auditory canal (Phelps P, personal communication).

Dehiscent superior semicircular canal syndrome

Dehiscent superior semicircular canal syndrome has been described. It can be demonstrated on high-resolution CT scanning. Typically, vertigo or oscillopsia is evoked by loud noises or by stimuli that result in changes in middle ear or intracranial pressure. The Tullio phenomenon (vertigo in response to sound) and Hennebert's sign (a positive fistula test with a normal middle ear) may therefore be found. Three-quarters of patients also experience chronic dysequilibrium – often the most debilitating symptom.[31] The condition may also present with an apparent conductive hearing loss. Evoked eye movements, by Valsalva manoeuvre against pinched nostrils, tragal compression or sounds over 100 dB at 500–2000 Hz, produce vertical and torsional components. Surgical repair via the middle fossa approach is successful. Radiologically, dehiscence in children is fairly common (27.3% of children under 2), but the degree to which this correlates with clinical symptoms is unclear.[32]

Perilymph fistulae

Perilymph fistulae in children are usually seen in association with temporal bone anomalies and pre-existing severe or total hearing loss in the affected ear. They may present with recurrent meningitis or with cerebrospinal fluid (CSF) behind the tympanic membrane. Perilymph fistulae can arise directly from blunt trauma to the middle ear or from temporal bone fractures and, iatrogenically, after ear surgery for CSOM or poststapedotomy. More rarely, marked barotrauma may lead to a fistula from the round or oval windows. In all these situations surgical exploration to seal the fistula is indicated. Spontaneous perilymph fistula in the normal temporal bone, however, is probably almost never seen.

In the late 1980s there was a vogue for clinically diagnosing a spontaneous perilymph fistula in children and adults who presented with symptoms of hearing loss, vertigo and sometimes tinnitus. These patients were subjected to surgical exploration of the middle ear with sealing of the apparent fistula. In general, the hearing outcomes from surgery did not seem to correlate with the finding of a fistula and, indeed, it can be very difficult at surgery to be sure if there is any real perilymph leak. To address some of the problems inherent in the diagnosis and treatment of perilymph fistulae, records of patients operated on at the House Ear Clinic over 12 years were reviewed retrospectively. Eighty-six patients were surgically explored for fistulae during this period. Thirty-five (40.7%) fistulae were found and 51 ears were patched whether fistulae were found or not. Of the 80 patients who were seen

for follow-up, 35 (43.8%) were subjectively better and 45 (56.2%) were the same. Although the number of fistulae found and the number of patients improved were similar, the composition of the two groups was different. On the basis of audiometric results, improvement in hearing happened in only 18.7% of patients. None of the demographic factors or diagnostic tests was predictive of either the presence of a fistula or the therapeutic outcome.[33]

Another retrospective study by Bluestone et al. on patients undergoing perilymph fistula repair compared pre- and post-operative hearing levels, vertiginous complaints and recurrences. In 92% of ears there was either stabilized or improved hearing and in 3% a decrease was noticed, but this was much later and believed not to be related. The results were similar, however, in the non-perilymph fistula ears, of which 95% had stabilized or improved hearing and, again, 3% had a much delayed decrease. Of the children with vertiginous complaints before surgery, 91% were improved or stable. Only one child felt somewhat worse, but, as with hearing loss, this was later than 6 months after the surgery.[34]

In yet another series of cases operated on for suspected perilymph fistula, ears with a surgically demonstrated fistula and sensorineural hearing loss had either flat or downward-sloping audiograms. At follow-up, vestibular symptoms were found to be eliminated or improved in 96% of cases with surgically demonstrated fistulae and in 68% of cases in which no fistula was detected at tympanotomy, but hearing improved significantly in only one ear (4%) of the former group and in five ears (20%) of the latter group.[35]

To conclude, perilymph fistulae can be a cause of hearing loss, vertigo or tinnitus and these symptoms may be fluctuant and possibly progressive. There is currently no good diagnostic test for a small fistula. In the paediatric population the most frequent cause is a congenital fistula. Severe or profound hearing loss is, in this instance, always associated with temporal bone anomalies when a perilymph/CSF leak may be present with fluid behind the tympanic membrane. A defect in the stapes and continuity with the fundus of the internal auditory meatus is one such example. This can be found with a true Mondini deformity, in which case some hearing from the basal turn of the cochlea is possible. These cases will require surgical exploration and closure of the leak, not to improve or restore hearing but in an attempt to prevent subsequent meningitis.

Traumatic perilymph fistulae with normal temporal bone anatomy are rare. They are described following head injury and penetrating injury to the middle ear with or without temporal bone fracture, but diagnosis is difficult.[36] A persistent perilymph fistula following ear surgery requires re-exploration. Severe barotrauma can also produce a fistula from the round window or oval window. Clinical suspicion will lead to the decision to explore the ear surgically. More obvious bony erosion with fistula is not infrequently encountered in the presence of cholesteatoma. Exploration and closure of the fistula is indicated. Spontaneous perilymph fistula, in the absence of head injury, direct injury or barotrauma can be virtually discounted.

Drug-induced vertigo or imbalance

Ototoxic medications, in particular aminoglycosides, can cause marked vestibular dysfunction with acute vertigo at the time of administration or poor balance, ataxia and motor delay. These drugs might have been administered systemically prenatally to the mother or in postnatal life, but occasionally topically in the presence of a chronic perforation or grommets. Fortunately, however, hearing loss from systemic aminoglycosides given to an infant is unusual. Some degree of vestibular loss may be more common and underdiagnosed. Streptomycin and gentamicin are more selectively vestibulotoxic. In one study, children who had previously been treated with streptomycin commonly showed delay in walking.[37]

Antimalarials such as mefloquine, which is cleared only slowly from the body, can cause dizziness or hearing loss. Platinum-based cytotoxic agents can cause ototoxicity, usually high-tone hearing loss and tinnitus rather than dizziness.

Miscellaneous conditions with hearing loss

Infectious aetiologies such as congenital cytomegalovirus (CMV) infection can include sensorineural hearing loss with vestibular symptoms and metabolic diseases such as Hurler syndrome can be seen with a retrocochlear type of hearing loss and vestibular impairment. Herpes zoster oticus can occur in children.

PERSISTENT IMBALANCE AND ATAXIA: CENTRAL DISORDERS

Toddlers may present with imbalance and a delay in motor development, or with a subsequent deterioration in vestibular function. They can have falls, fear of the dark, abnormal gait and vomiting. Primary developmental delay with motor delay and poor balance suggests a congenital or early acquired neurodevelopmental disorder, while regression of balance and locomotor function that was previously acquired indicates the need to exclude a space-occupying lesion such as meningioma or medulloblastoma. A family history of NF2 would raise suspicion. Any severe illness or even major surgery in a baby or smaller child will not infrequently lead to temporary loss of previously acquired skills such as the ability to walk.

ATAXIA

Ataxia is a common mode of presentation of cerebellar, posterior column and vestibular disease in children. The aetiology of ataxia covers a broad range, from infections to rare hereditary metabolic diseases. The importance of recognizing potentially reversible conditions such as vitamin E deficiency and Refsum's disease has been stressed.[38]

Hereditary cerebellar ataxia

Hereditary cerebellar ataxia presents with a slowly progressive ataxia although a posterior fossa tumour must be excluded by imaging. Cerebellar disorders display a variety of inherited and sporadic causes. Advances in genetics have led to the successful classification of over 20 forms of autosomal dominant and recessive cerebellar ataxia with variable phenotypes and have shed light on the underlying pathophysiology of many of these disorders. Successful disease-modifying or symptomatic treatments for these conditions, thus far, have remained limited.[39]

Refsum's disease

Refsum's disease is a disorder of lipid metabolism with pigmentary retinopathy, demyelinating neuropathy, ataxia and hearing loss. There is progressive difficulty in walking which develops between the ages of 4 and 7 years. In some cases the site of the hearing abnormality in Refsum's disease may be 'post-outer hair cells'.[40]

Charcot–Marie–Tooth disease

The most common hereditary degenerative condition is Charcot–Marie–Tooth disease. Inheritance is autosomal dominant. Perineal muscle atrophy is usual, congenital sensorineural deafness is present in some cases and there can be vestibular weakness. These children develop spinal scolioses and pes cavus.[41]

Acute cerebellar ataxia

Acute cerebellar ataxia occurs, usually in the first 3 years of life, in a child who was previously normal. It follows a viral febrile illness a few weeks beforehand. There is sudden ataxia, and the condition may take a number of months to resolve or leave some permanent sequelae. Neuroimaging should be considered in all children with new-onset ataxia.[42]

Chiari malformations

Type 1 Chiari malformation is characterized by cerebellar tonsil herniation through the foramen magnum. Children most commonly present with bilateral vocal cord paralysis and associated upper airway obstruction but they can also present with positional vertigo and a central type of nystagmus. The condition can be more severe and associated with syringomyelia, in which case there can be neurological improvement after foramen magnum surgical decompression. Type 1 may present to otolaryngologists.

Type 2 Chiari malformation is the same as type 1, except that in addition there is a non-communicating hydrocephalus and lumbosacral spina bifida. Type 3 can have any of these features but with cervical or occipital bifida. Children with types 2 and 3 have widespread neurological abnormalities and are unlikely to attend ENT clinics.

Miscellaneous conditions

Demyelination can present in post-pubertal children, in which case vertigo is quite commonly seen. NF2 with posterior fossa meningiomas or vestibular schwannoma are occasionally seen in children, and other intracranial posterior fossa lesions such as medulloblastoma may present with ataxia and vomiting.

Infectious causes

Infectious causes include Lyme disease. Viral infections include meningitis, Coxsackie A and B and echovirus; they can involve the central nervous system with vertigo, nystagmus and cerebellar signs. HIV infection is another possible cause. Bacterial infections include primary meningitis, labyrinthitis as a complication of meningitis or CSOM and tertiary or congenital syphilis.

TREATMENTS FOR VERTIGO

Medical treatments

The causative condition should be treated directly if possible. The mainstay of treatment, however, is usually an explanation to the parents and the child and reassurance.

Symptomatically, vestibular sedatives can be helpful. Antihistamines such as cyclizine or cinnarizine can be taken for more prolonged attacks. Hyoscine patches have been advocated and domperidone is helpful for associated sickness. Use should be limited to acute attacks rather than for chronic symptoms.

Dopamine antagonists including phenothiazines such as prochlorperazine are effective vestibular suppressants. However, there is a greater risk of extrapyramidal side effects when using phenothiazines, especially in children. They should be avoided in babies under 10 kg. Should these medications lead to extrapyramidal effects such as oculogyric crisis, it can be treated acutely with the antagonist, procyclidine, by injection.

HT3 antagonists such as ondansetron are powerful antiemetics, which block serotonin binding at vagal afferents in the gut and in the regions of the central nervous system (CNS) involved in emesis, including the chemoreceptor trigger zone and the nucleus tractus solitarii. Although principally used in post-operative nausea and vomiting or with cytotoxic drug therapy, they may have a role in the vertiginous child, especially if vomiting.

Attacks of vestibular migraine can be treated with domperidone, cinnarizine or cyclizine for nausea, vomiting or dizziness. Serotonin 5-HT1B/1D receptor agonists such as sumatriptan may be useful in management of headaches. Rizatriptan is reported to be more effective than other drugs of this class and other simple analgesics.[14] Preventative measures, if necessary, would be those currently recognized – pizotifen or propanolol – and if those fail, a neurologist might prescribe the full range of antimigraine medications available to use in adults.[16] Topiramate and flunairizine have randomized double-blind placebo-controlled trials in

children that support their use, and there are open label studies in favour of sodium valproate.[14]

Menière's disease may be treated with betahistine, a low-salt diet and possibly diuretics or intermittently by dehydration therapy such as glycerol taken orally. Surgery may occasionally be indicated in severe variants of the disease.

The seizure disorders are usually well controlled with anticonvulsants under the paediatric neurologist's guidance.

Physical treatments for vertigo

If there is benign positional vertigo, the Epley manoeuvre (see Chapter 64, Benign paroxysmal positional vertigo) can be employed successfully. Other vestibular rehabilitation exercises for children who have suffered unilateral labyrinthine damage might be helpful in achieving full central compensation and in speeding recovery.

Surgery for vertigo

Surgery relates to that indicated for specific underlying conditions. Unilateral glue ear with poor balance can be corrected by insertion of grommets (preferably bilaterally, the contralateral ear as a prophylactic measure).

If there is a perilymph fistula from barotrauma, middle ear or mastoid disease, or following surgery, that should be explored and closed. Likewise, suppurative ear disease and congenital or acquired cholesteatoma will require tympanomastoid surgery.

A perilymph/CSF fistula from congenital temporal bone anomalies should be closed surgically in an attempt to prevent future meningitis.

Childhood-onset Menière's disease tends to run an aggressive course with debilitating bilateral disease later in life. Destructive surgery is not advised at an early stage although endolymphatic sac decompression and drainage may have a role.

BEST CLINICAL PRACTICE

- ✓ A full history, neurotological examination and audiometry are required in assessing any child with vertigo.
- ✓ Middle ear disease and congenital sensorineural conditions with vestibular deficits should be excluded.
- ✓ Posterior fossa disease must be excluded where there is ataxia.
- ✓ In some cases, a full blood count, inflammatory markers, glucose, creatinine kinase, thyroid function and special serological tests are helpful.
- ✓ High-resolution CT scanning of the temporal bones and an MR brain scan are often indicated for dizziness with hearing loss.
- ✓ An MR brain scan is indicated for ataxic conditions.
- ✓ Special vestibular tests including bithermal caloric stimulation and rotational chair testing can be helpful in reaching a diagnosis and planning treatment.
- ✓ Referral to a paediatric neurologist is recommended if the diagnosis of a seizure disorder or basilar-type migraine is considered probable.
- ✓ Treatment should comprise explanation and reassurance about the condition and symptomatic medical treatment for the vertigo.
- ✓ Surgical treatment is recommended for significant balance disturbance with OME and for CSOM with cholesteatoma as well as for a persistent perilymph fistula from other causes.

FUTURE RESEARCH

- ➤ The value of bithermal caloric tests, videonystagmography and rotational chair tests has not been demonstrated in the varied paediatric population with vertigo.
- ➤ The benefit of vestibular rehabilitation exercises overencouraging straightforward everyday activities has not been studied in children's treatment regimens.
- ➤ Motion sickness has been subject to observational studies and effects of drug treatments but further research into aetiology and other treatments could be profitable.
- ➤ The role and efficacy (if any) of HT3 antagonists such as ondansetron in the management of childhood vertigo has not been studied.

KEY POINTS

- Vertigo results from a mismatch of three different sensory inputs for balance, i.e. vision, proprioception and the vestibular system.
- Presentation of balance disorders in children differs from that in adults; very young children cannot complain of vertigo.
- Fifty percent of cases of childhood dizziness and imbalance are caused by one of the three most common causes: BPV of childhood, migraine or OME.
- Neurological disease is a rare cause of vertigo in children but must be recognized.
- Adult causes of vertigo are seen in older children/adolescents.
- The mainstay of treatment is reassurance; symptomatic control with medication such as cinnarizine or antimigraine treatments is usually effective.

CHAPTER 21

FACIAL PARALYSIS IN CHILDREN

S. Musheer Hussain

SEARCH STRATEGY

Data in this chapter may be updated by a PubMed search using the following keywords: facial paralysis, otitis media, congenital facial paralysis, ear trauma, facial nerve injury, granulomatosis with polyangitis, Bell's palsy and parotid surgery. The focus was restricted to neonates and children.

INTRODUCTION

Bell's palsy remains the most common aetiology for facial paralysis in children[1] although it is much less common than in adults. In their study of 170 patients aged from birth to 18 years May et al.[2] found the following aetiology for facial paralysis: Bell's 42%, trauma 21%, infections 13%, congenital 8% and neoplasm 2%.

Bell's palsy in children is considered to have a better prognosis than in adults, regardless of treatment.

EMBRYOLOGY AND APPLIED ANATOMY OF THE FACIAL NERVE

Knowledge of the embryology and developmental anatomy of the facial nerve allows for a clear understanding of the various anomalies and clinical presentations of disorders of the facial nerve.

By the third week of embryonic development the facioacoustic crest is visible on the dorsolateral aspect of the hindbrain just cranial to the otic placode. The otic placode forms the otocyst, giving rise to the membranous labyrinth in the fourth week and the facial nerve becomes distinct. The geniculate ganglion has formed by the fifth week (Figure 21.1). The facial nerve divides into its main trunk, descending into the second branchial arch and the chorda tympani, which being the pretrematic branch curves cranially into the first branchial arch (Figure 21.1).

A pretrematic branch of a cranial nerve is one that supplies the arch preceding the arch to which the cranial nerve belongs. The chorda tympani and the main trunk of the facial nerve are equal in size at this stage. Malformations of the branchial arches are associated with anomalies of the chorda tympani such as elongation of the posterior canaliculus, reduplication and low position of the nerve.[3–4]

The facial nucleus is formed by neuroblasts in the pons, with the sixth nerve nucleus in close proximity. As the brain develops and the pons expands, the sixth nucleus ascends so that the facial nerve fibres have to whirl round the sixth nucleus forming an internal genu. Clinically, therefore,

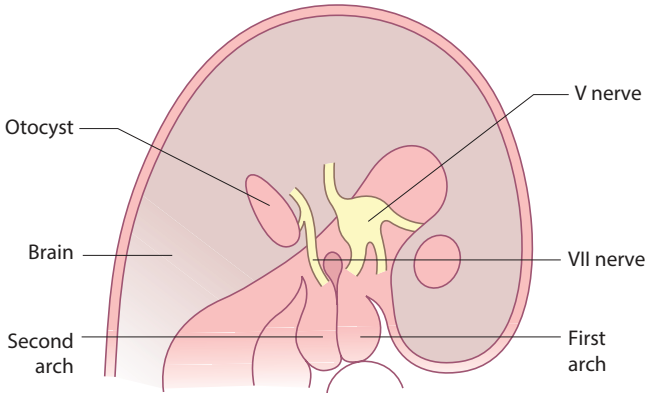

Figure 21.1 Line diagram of the fetal head at 5 weeks, showing the facial nerve.

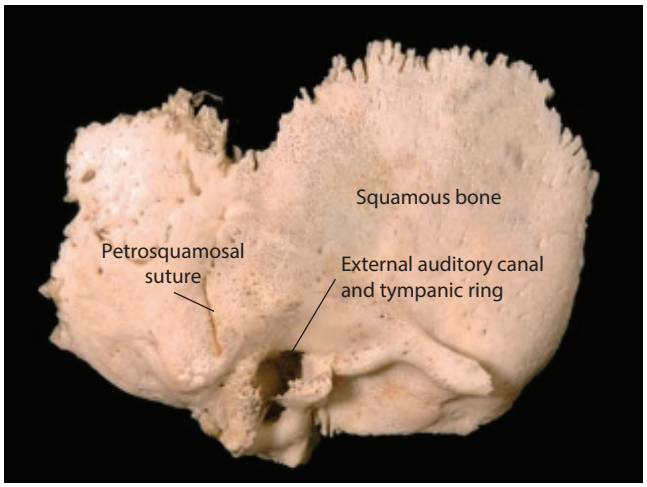

Figure 21.2 Neonatal temporal bone.

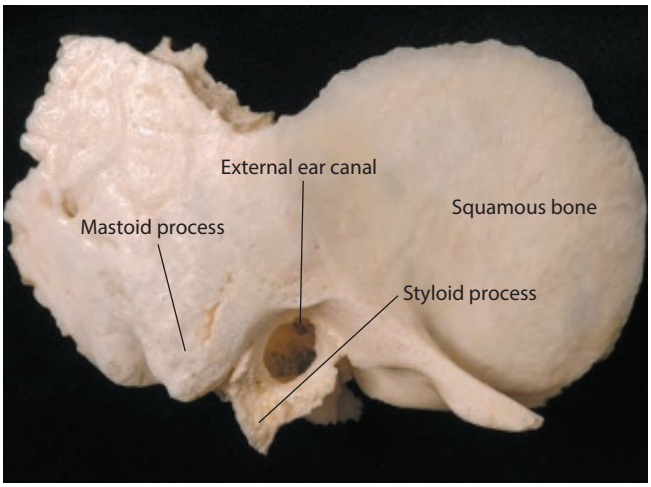

Figure 21.3 Temporal bone of a 1-year-old child.

an inflammatory or vascular event in this part of the brain will necessarily involve both these nerves. In developmental anomalies such as Moebius syndrome there is agenesis of the facial nucleus and among other defects there is also agenesis of the sixth nucleus.[5]

The geniculate ganglion has a separate origin from the facial nerve.[6] It is well defined by the seventh week and gives rise to the sensory roots that form the nervus intermedius. As the main facial trunk descends down the second branchial arch there is caudal movement of the first arch due to rapid expansion, producing the horizontal segment and the first and second genu of the vertical nerve with the greater superficial petrosal nerve acting as an anchor. Proctor and Nager's seminal papers[7, 8] describe the many variations encountered in the vertical segment of the facial nerve including a bipartite nerve, an anteriorly displaced nerve or one with a posterior hump. Failure to appreciate an anomaly of the facial nerve during surgery can have serious consequences.[9–12] Conditions related to malformations of the first or second arch such as Treacher Collins and Goldenhar syndromes will usually mean that the facial nerve is abnormal too.

At birth the normal temporal bone has no mastoid process and an incomplete tympanic ring. The 'U-shaped' tympanic ring has nodular prominences on each arm, which separate the annulus from the future external canal and the foramen of Huschke (**Figure 21.2**). By the end of the first postnatal year these processes fuse, lengthening the canal (**Figure 21.3**). The foramen usually closes some time later. The chorda tympani and the facial nerve may exit through the stylomastoid foramen in the newborn. The mastoid process and external auditory canal are undeveloped so the nerve is very superficial.

The mastoid process develops and reaches adult proportions by the age of 12 years. In neonates and small children the second genu of the facial nerve is more acute and courses more laterally. The most common variation in the course of the facial nerve canal involves the tympanic segment; the bony wall may be dehiscent in 35–55% of the population particularly above the oval window.[7, 8, 13, 14] Acute suppurative otitis media in neonates and children may therefore present with facial paralysis from neuropraxia or bacterial infiltration of the nerve sheath within an enclosed middle ear. Dehiscence of this segment of the facial nerve may be associated with a persistent stapedial artery in its course from the tympanic cavity to the middle cranial fossa where this becomes the middle meningeal artery.[15, 16] The foramen spinosum is absent on the side of the persistent stapedial artery on plain X-ray or CT.

On leaving the stylomastoid foramen the facial nerve enters the parotid gland in a more anterior location than in the adult, as the parotid gland is smaller and more anteriorly placed.[17] The nerve divides into two main divisions and these give rise to branches that supply the face and the upper neck muscles. The lower division of the facial nerve in young children runs very superficially over the angle of the mandible and can be damaged by a skin incision during surgery.

Surgery of the parotid region in children requires an understanding of the differences between adult and child facial nerve topography (**Table 21.1**).

DIAGNOSIS

This is discussed in general terms in this section. Individual conditions are covered under separate headings.

History taking and examination

A detailed clinical assessment is important in the diagnosis of facial paralysis. There may be good muscle tone so that it is difficult to identify the paralysis until the child cries. Associated symptoms that teenagers with facial paralysis may volunteer will not be available in a younger child. Careful attention to the mother's story will be rewarding.

Examination should include careful assessment of each branch of the facial nerve and whether the paralysis is complete or incomplete. The forehead wrinkles are absent and the eyebrow droops in lower motor neuron paralysis. The lower lid tends to fall away from the globe with tears

TABLE 21.1 Differences in the anatomical relationship of the facial nerve in adults and children

Feature	Child	Adult
Mastoid process and tympanic ring	Absent mastoid process and incomplete tympanic ring. The chorda tympani may exit through the stylomastoid foramen with the main trunk in the neonate	Mastoid process present and tympanic ring is complete by adolescence. The chorda tympani exits separately and proximal to the stylomastoid foramen
Second genu of facial nerve	Second genu of the facial nerve is more acute and more lateral	Second genu of the facial nerve is less acute and more medial
Position of nerve trunk	Nerve trunk on exit from the stylomastoid foramen is more anterior and lateral	Parotid is more posteriorly placed and the nerve trunk is less anterior and deeper
Position of nerve	Nerve very superficial over the angle of the mandible	Nerve less superficial over the angle of the mandible

collecting in the eye and spilling onto the face. The cheek may sag and the nasolabial fold may be lost. Speech may change as plosives are distorted with air blowing out on the paralysed side. The appearance of the non-paralysed side of the face is also characteristic as unbalanced muscle action accentuates the difference. The House Brackmann grading is limited but has the advantage of being widely known and may be used in children. Otoscopy is usually possible in even the smallest baby and signs of inflammation should be looked for in the head and neck. Other anomalies of the head and neck and the cranial nerves are noted.

Investigations

IMAGING

Imaging of the facial nerve in children may be useful in delineating the site of neural injury. Indications include persistent paralysis, trauma and suspected nerve involvement in systemic diseases.

MRI is the only modality that demonstrates the facial nerve comprehensively from the pons to the parotid gland; with gadolinium enhancement it is capable of showing inflammatory changes. CT makes it possible to see bony detail and is ideal when facial nerve involvement is in the middle ear cleft.

ELECTROPHYSIOLOGICAL TESTS

Electrophysiological tests allow objective assessment of function. Eavey et al.[18] found that 95% of children can be successfully tested with electroneurography (ENoG). Waveform amplitude and morphology were consistent with adult values except in infants. The most clinically helpful use of this test is to objectively assess facial nerve function, once spontaneous motion is lost in acquired paralysis or if it had never been seen in congenital paralysis. The authors maintain that the test is not an absolute predictor for return of function but that the added data when used with clinical information make assessment of prognosis more rational.

Glassock and Shambaugh[19] recommend a muscle biopsy in neonates with facial paralysis when the electromyography is silent. If muscle is found early, reanimation is advisable.

CONGENITAL FACIAL PARALYSIS

Syndromic and non-syndromic forms of developmental facial paralysis occur. These may be unilateral or bilateral, complete or incomplete. Prognosis is poor.[20, 21] Craniofacial anomalies associated with the first and second arch derivatives are common in this form of facial paralysis.

Nerve exploration is unrewarding in this situation.[22] Reanimation may be considered. There is a wide range of procedures for reanimation; the most desired neural tissue source for rejuvenation of the paralysed face is direct reanastomosis or interpositional grafting. Carr et al.[23] reviewed 186 children with congenital facial paralysis (60% male and 85% with bilateral paralysis) and found 29 in whom reanimation was performed (24 females and 5 males). All 5 males and 9 females had unilateral isolated facial nerve paralysis. Fourteen females had bilateral paralysis; only half of these were isolated. Other involved cranial nerves included abducens, hypoglossal, oculomotor and trochlear. The cranial nerve least likely to be involved was the accessory nerve, suggesting that this may be a reliable donor for reanimation procedures. As previously stated, early reanimation is advised by Glassock and Shambaugh[19] if muscle is found on biopsy in neonates with facial paralysis when electromyography is silent.

Moebius syndrome

Moebius syndrome is a rare cause of facial paralysis in neonates. It is characterized by the absence or underdevelopment of the sixth and seventh cranial nerves. It may be unilateral or bilateral. Agenesis of the facial nucleus is suspected, hence the sixth nerve involvement. Other cranial nerves may also be involved. Autism and mental retardation may be seen in a third of these patients.[5]

Goldenhar syndrome

Goldenhar syndrome (oculo-auriculo-vertebral dysplasia) is a wide spectrum of congenital anomalies that involves structures arising from the first and second branchial arches.[24] Involvement of the internal auditory meatus and the eighth nerve has been reported[25] as well as progressive hearing loss.[26]

Asymmetric crying facies

Congenital asymmetric crying facies is an uncommon condition caused by congenital hypoplasia or agenesis of the depressor anguli oris muscle on one side of the mouth. Although the functional deficit is small, the anomaly may be associated with cardiovascular, head and neck, musculoskeletal, respiratory, gastrointestinal, central nervous system or genitourinary anomalies in 45% of cases.[27]

CHARGE syndrome

The acronym CHARGE is used to describe specific congenital birth defects in children: **c**olobomata, **h**eart defect, **a**tresia of the choanae, **r**etarded development, **g**enital hypoplasia, and **e**ar anomalies and hearing loss. Facial nerve dysfunction has been noted in 38% of patients,[28] and an aberrant course may interfere with cochlear implantation.[29] Many children with the CHARGE association also have feeding and swallowing difficulties, and facial paralysis and pharyngeal in-coordination may be important diagnostic indicators of CHARGE association.[30]

Familial facial paralysis

Familial congenital facial paralysis has been reported in three male members from three generations in a family.[31] The paralysis becomes more pronounced with every successive generation.

Widening of the facial canal

Widening of the facial canal has been reported as a cause of multiple ipsilateral facial palsy in a child of 13 months.[32] The child had recurrent fever and facial palsy and the facial nerve appeared thickening in the widened canal, said to be the result of pressure from inflammation and oedema.

Figure 21.4 (a) Facial paralysis in a neonate caused by acute otitis media; **(b)** the state of the eardrum.

ACQUIRED FACIAL PARALYSIS

Infections

ACUTE OTITIS MEDIA

Acute otitis media in neonates and children gives rise to facial paralysis (**Figure 21.4a**). This is usually incomplete but the paralysis may progress in the first 2–3 days of onset. There is suppuration in the middle ear behind an intact tympanic membrane, which may appear red and bulging (**Figure 21.4b**). The child may be toxic but is typically not unwell. In some cases where antibiotics have been given, the signs of acute inflammation may not be pronounced.

The underlying pathology may be an erosion of the bony Fallopian canal or congenital dehiscence and nerve inflammation. Spread along structures such as the stapedial tendon, chorda tympani or posterior tympanic artery has been suggested. Moreano et al.[14] studied 1000 temporal bones and noted at least one facial canal dehiscence in 56% of temporal bones with the most common site of dehiscence being the oval window area. They introduced the concept of micro-dehiscence of the facial canal and found this in one third of the temporal bones. The most common pathogen in middle ear cleft infections in children is pneumococcus[33] (80%). A wide myringotomy and systemic antibiotics is the initial treatment. If mastoiditis is suspected, a CT scan and a cortical mastoidectomy may be needed. There is usually full recovery of facial nerve function.

CHRONIC OTITIS MEDIA

Facial paralysis in chronic otitis media is very uncommon. Sheehy et al.[34] report 11 cases of facial paralysis out of 1024 patients with chronic middle ear disease and cholesteatoma. Complications of chronic middle disease including facial paralysis are more common in the developing world.[35]

LYME DISEASE

This multisystem disease is caused by the tick-borne spirochaete *Borrelia burgdorferi*.[36] The incubation period is

1–4 weeks before a skin lesion appears. Ipsilateral or bilateral facial paralysis may appear weeks or months later in 11% of cases.[37] A report from Connecticut, an endemic area, describes Lyme disease as the cause of over 50% of facial paralysis in children.[38] Serological tests with ELISA (enzyme-linked immunosorbent assay) to detect IgG and IgM antibodies are used for diagnosis. Doxycycline is the oral antibacterial of choice, while amoxicillin and cefuroxime are alternatives that may be preferred in young children. Tick avoidance has long been the mainstay for preventing Lyme disease.[39]

VIRAL INFECTIONS

Recrudescence of *Herpes zoster* virus in the geniculate ganglion leads to the classical syndrome of Ramsay Hunt. The disease is uncommon in children. Hato et al.[40] in a retrospective study of 52 children with Ramsay Hunt syndrome found that facial paralysis was milder, complete recovery of the function more likely (79%) and associated cranial neuropathies less common in children than in adults. The timing of vesicle appearance tended to be delayed in children. The disease was rare in preschool children but relatively more common in older children. Treatment with oral or intravenous acyclovir and prednisolone has been recommended.[41–43]

Facial paralysis has been noted in Epstein–Barr virus infection and this may be bilateral in 40% of cases.[44] Facial palsy is an early ENT manifestation of HIV infection and is seen in 11% of cases.[45]

TUBERCULOSIS

The presence of facial paralysis with purulent otorrhoea that does not respond to conventional antibiotics should alert the physician to the possibility of tuberculosis. Antituberculous chemotherapy early in the disease may reduce the need for radical surgery[46, 47] and complications of otitis media.[48] CT scan is reported to be of value in the diagnosis of facial paralysis due to tuberculosis.[49]

Traumatic

BLUNT TRAUMA

Perinatal trauma

Birth-related trauma is a known cause of facial paralysis. The incidence of facial palsy in the newborn is 1.8 in 1000, the majority associated with forceps delivery.[50] In their report on neonatal facial paralysis, Smith et al.[51] found 74 out of 95 cases to be secondary to trauma associated with pregnancy and delivery. The diploic bone of the infant mastoid process, the paper-thin bone covering the facial nerve and the very superficial position of the marginal mandibular branch over the mandible all add to the problem. The pressure of the mother's sacrum on the infant facial nerve may also contribute.

In differentiating between congenital and perinatally acquired facial paralysis, the history and physical examination usually suffice. A history of forceps delivery, a baby weighing over 3.5 kg, a primipara mother, prolonged labour and the absence of associated craniofacial anomalies point to perinatal trauma as the cause. The presence of bruising of the side of the face and the mastoid region are suggestive of birth trauma, as are other complications associated with birth.

Electrophysiological tests may be used to aid diagnosis; voluntary action potentials on electromyography (EMG) indicate muscle innervation. EMG performed after 10 days of paralysis will show fibrillation or polyphasic potential in traumatic cases and absent electrical activity in congenital facial paralysis.[52] A CT scan may show a concealed fracture of the temporal bone.

Temporal bone fracture

An injury to the skull may cause temporal bone fracture. The fracture may be longitudinal or transverse or a combination of both. Classically, longitudinal fractures cause conductive hearing loss whereas transverse fractures usually cause irreversible sensorineural deafness. A third of fractures are transverse and these have associated facial paralysis in 50% of cases. Longitudinal fractures are more common and, although the incidence of facial paralysis is less (20%), longitudinal fractures cause more facial paralysis than transverse fractures. As discussed under embryology, the greater superficial petrosal nerve in the region of the geniculate ganglion tethers the facial nerve. In head injury the sudden deceleration creates a shearing force on the facial nerve leading to damage. Lee et al.[53] reviewed 72 children with temporal bone fractures ranging from 6 months to 14 years of age, with a bimodal distribution with peaks at 3 years and 12 years of age. The most common causes of fractures were motor vehicle accidents (47%), falls (40%), biking accidents (8%) and blows to the head (7%). Common presenting signs and symptoms[53] include hearing loss (82%), haemotympanum (81%), loss of consciousness (63%), intracranial injuries (58%), bloody otorrhea (58%), extremity fractures (8%) and facial nerve weakness (3%). The diagnosis of temporal bone fractures is best made clinically and radiographically.

The early care of temporal bone fractures is directed towards the treatment of CSF otorrhoea and immediate-onset facial paralysis. The delayed care is primarily concerned with hearing rehabilitation.[55]

Another classification[56] of temporal bone fractures is based on otic capsule sparing (OCS) and otic capsule violating (OCV) fractures. The otic capsule is spared in 90% of fracture and is a predictor of the absence of sensorineural hearing loss. However, conductive hearing loss or facial paralysis cannot be predicted by the OCS/OCV classification.

Surgical exploration as an option remains controversial, with no randomized controlled study. It does seem reasonable, however, to explore when nerve entrapment is suspected or where the integrity of the nerve is compromised.

PENETRATING TRAUMA

Injury to the face may damage the facial nerve or one or more of its branches. This may be the result of falling

onto a sharp object or a dog bite. The wound needs to be explored and the degree of damage established. This will allow repair with the functioning distal branches in a clean wound. Local control of infection should precede repair in a contaminated wound.

IATROGENIC TRAUMA

Ear surgery

Mastoid surgery in children caries a higher risk of injury to the facial nerve, even in experienced hands. This is due to the absence of the mastoid process in small children and the superficial position of the facial nerve, which is at risk from a low incision. The operating space within the mastoid cleft is small and, if in addition an anomaly is encountered, the problems multiply. The injury may not be identified at the time of surgery and may become obvious when the patient is awake.[57] The commonest site of injury is the tympanic segment and the second genu of the nerve.[58, 59]

Anomalies of the facial nerve encountered in patients with congenital malformation of the middle ear include displacement of the nerve and lack of bony cover.[10] A low-lying tegmen in a sclerotic mastoid is particularly serious and requires skill to protect the nerve at the second genu when drilling in this restricted area. The presence of granulating disease in revision surgery may obscure the usual landmarks and put the nerve at risk. Erosion of the bone by cholesteatoma and its spread to the supra tubal recess[59] puts the geniculate ganglion and the first genu of the facial nerve at risk of injury during disease clearance in the anterior attic. In patients with atresia or stenosis of the external canal the facial nerve may be damaged in its vertical segment due to the vertical segment being relatively lateral to the tympanic annulus. Intra-operative monitoring is advisable.

Injury to the facial nerve and the chorda tympani are recognized complications of cochlear implantation surgery.[60–62]

Parotid surgery

The superficial course of the facial nerve in infants and the underdevelopment of surrounding structures mean that the standard techniques for identification of the facial nerve trunk in adults could jeopardize the nerve in children. An alternative technique for identifying the facial nerve has been proposed by Farrior et al.[17] Anatomic dissections demonstrate that the facial nerve trunk can be consistently found in a triangle formed by the sternocleidomastoid muscle, posterior belly of the digastric muscle and the cartilaginous ear canal. As in the adult, the nerve canal can be identified in the mastoid cavity and followed into the neck. Unlike in the adult, it is inadvisable to use retrograde dissection of the marginal mandibular branch to find the trunk. If surgery is considered for non-tuberculous mycobacteria (NTM) of the intraparotid and adjacent lymph nodes, very careful dissection is required to preserve the facial skin and the nerve (**Figure 21.5**) (see Chapter 37, Cervicofacial infections).

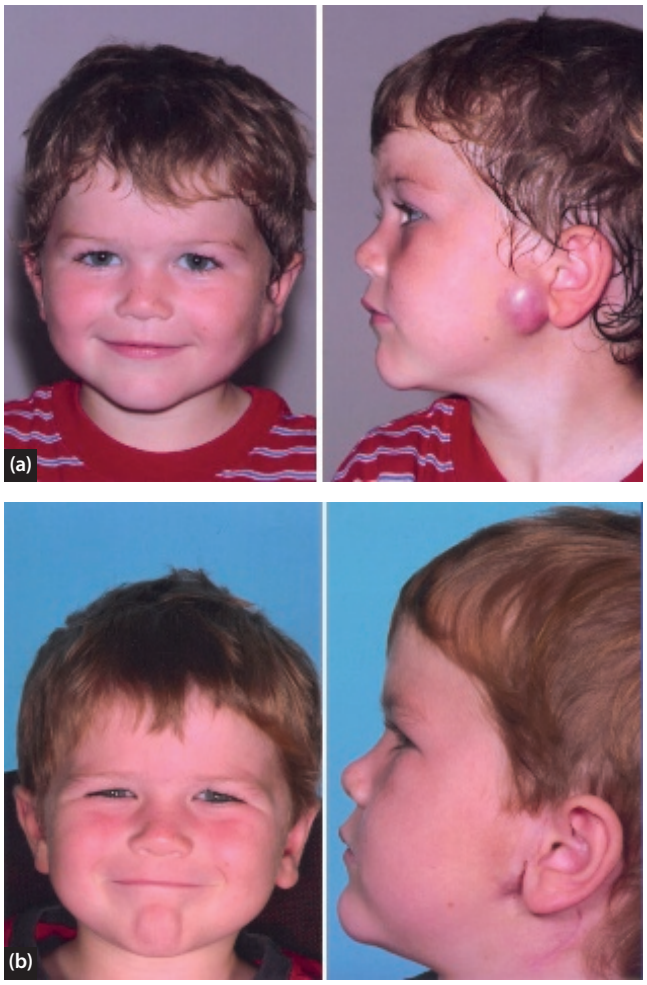

Figure 21.5 Non-tuberculous mycobacteria (NTM) of the parotid. (a) Presurgery; **(b)** 1 week after surgery with preservation of the facial nerve.

Branchial cleft sinus and fistula excision

The variable relationship of the branchial cleft sinus and fistula with the facial nerve makes the nerve vulnerable to injury during surgery. Very careful dissection with intra-operative monitoring is required. D'Souza et al.[63] reviewed the available English, French and German literature between 1923 and 2000 and found 158 cases with fistulae and sinuses. The fistulous tracts were more likely to lie deep to the facial nerve compared with sinus tracts. Lesions with openings in the external auditory meatus were associated with a tract superficial to the facial nerve. Younger children were more likely to have a deep tract with consequent increased risk of facial nerve damage. The fistula may be found anywhere along the anterior border of the sternocleidomastoid muscle.[64]

Solares et al.[65] in their report on ten patients with a mean age of 9 years found seven lesions medial to the

facial nerve, two lateral and one between branches of the facial nerve. (See also Chapter 41, Cysts and sinuses of the head and neck.)

Neoplasms

In children the two commonest causes of facial paralysis from malignancy are leukaemic infiltration of the temporal bone[66, 67] and rhabdomyosarcoma of the head and neck.[68–70] An intracranial tumour may present with facial palsy. Levy et al.[71] describe a case of acute mastoiditis and facial paralysis in a 5-year-old girl where the diagnosis of leukaemic infiltration of the middle ear cleft was made only after surgery and histological examination. Chemotherapy or combined chemo- and radiotherapy are the treatment of choice in known leukaemic patients without symptoms of superimposed infection of the ear or the mastoid process. Surgical management is restricted to cases in which tissue for histological diagnosis is required or drainage of acute infection is needed. A T-cell lymphoblastic lymphoma in the middle ear has been reported,[72] presenting with headaches, hearing loss and facial palsy in an 11-year-old that responded to intensive chemotherapy.

In the Durve et al.[68] series of 14 patients the median age at presentation of rhabdomyosarcoma was 4.5 years with a mean time of onset of symptoms to diagnosis of 21 weeks. Symptoms mimicked those of chronic otitis media, delaying diagnosis. The histological subtype was embryonal in 13 patients and alveolar in 1. All patients underwent multimodality treatment; the 5-year disease-free survival rate was 81%. Facial paralysis was the commonest regional post-treatment morbidity (8/14).

The presence of facial paralysis and lymphadenopathy or a mass with aural discharge, hearing loss and aural polyp should prompt urgent investigation and biopsy.

Benign neoplasm of the facial nerve is very rare in children. Facial paralysis from an intracranial neoplasm is uncommon.

IDIOPATHIC FACIAL PARALYSIS

Bell's palsy

Bell's palsy is the commonest cause of facial paralysis during childhood (42%).[2] It is an acute unilateral lower motor neuron facial paralysis diagnosed by exclusion. It is essential that otoscopy is normal, that there is no middle ear infection and that the hearing is not impaired. There is a body of opinion that attributes Bell's to infection by herpes virus due to a reactivation of latent *Herpes simplex* virus within the geniculate ganglion though the evidence for this is uncertain. There is a family history of Bell's palsy in a small number of patients and occasionally a viral prodrome.

Steroids are advocated in the acute stage for adults, with good evidence from a large randomized controlled trial to support this.[73] There is little evidence either way for children, however, and since the recovery rate is so high in children regardless of treatment (90%), it has been suggested that steroid administration is not required in children.[74]

Melkersson–Rosenthal syndrome

In Melkersson–Rosenthal syndrome, episodes of facial paralysis begin in early childhood or adolescence, predominately in the second decade of life. There is swelling of the lips, palatal mucosa and face, and the tongue is fissured.[75] The facial weakness usually takes a recurring course and is seen in 20% of cases. A conservative approach is usually recommended. A preliminary report suggesting facial nerve decompression for recurrent facial paralysis in Melkersson–Rosenthal syndrome has recently been further substantiated.[76–79]

Granulomatosis with polyangiitis

Granulomatosis with polyangiitis (formerly known as Wegener's granulomatosis) is a systemic disease characterized by the classical triad of vasculitis, necrosis and granulomatous inflammation usually of the upper and lower respiratory tract and the kidneys. Primary otological presentation occurs in 20–25% of patients[80] and this includes facial paralysis.[81] A high index of suspicion, ESR, cANCA and histopathology help diagnose this condition. Combination therapy with corticosteroids and cyclophosphamide is given and cotrimoxazole may be used in the long term to reduce remissions.[82]

Hypertension

Hypertension is a rare cause of facial paralysis in children. Misdiagnosis may lead to serious consequences, as reported by Aynaci and Sen[83] in a case of a hypertensive child with facial paralysis. Bell's palsy was suspected and steroids were given, resulting in hypertensive pontine haemorrhage. Recurrent alternating facial paralyses have been reported in a child with hypertension. Antihypertensive treatment and control lead to cessation of further relapse.[84] A recent systematic review of facial palsy in patients with hypertension found 26 cases, of which 23 were children.[85] The palsy is usually unilateral and may recur in a quarter of cases.

CONCLUSION

The management of facial palsy in children includes treatment for eye exposure, smile asymmetry, drooling and lack of labial function and synkinesis. Free tissue transfer dynamic restoration is the preferred method for smile restoration[86] in this population. The outcomes are apparently better than in adults.

BEST CLINICAL PRACTICE

- ✓ MRI is the only imaging modality that demonstrates the facial nerve comprehensively from the pons to the parotid gland; with gadolinium enhancement it is capable of showing inflammatory changes.
- ✓ Electroneurography is a useful adjunct to clinical findings in predicting recovery from facial nerve palsy.
- ✓ In facial palsy secondary to acute otitis media optimum management is wide myringotomy and systemic antibiotics.
- ✓ Congenital and acquired facial paralysis in the neonate can be differentiated on the basis of examination supplemented as required by electrophysiologic investigations.
- ✓ It is standard practice to have facial nerve monitoring during parotid and tympanomastoid surgery in children with a high incidence of anatomical abnormalities of the facial nerve, e.g. Down syndrome, craniofacial anomalies.
- ✓ Retrograde dissection of the marginal mandibular branch of the facial nerve to find the trunk is particularly unreliable in children.

FUTURE RESEARCH

- ➤ The treatment for facial paralysis in children remains largely empirical; randomized controlled trials may help answer some of the questions. In view of the small number of cases and the generally good prognosis, multicentred trials with sufficiently large numbers of cases are required.
- ➤ The currently available monitoring systems for facial nerve function during surgery lack total reliability and are limited in scope.

KEY POINTS

- The commonest cause of facial paralysis in children is Bell's palsy.
- Knowledge of the embryology and developmental anatomy of the facial nerve allows for a clear understanding of the various anomalies and clinical presentations of disorders of the facial nerve.
- There are important anatomical differences between the topography of the facial nerve in adults and children.
- These differences and the confined surgical space can make tympanomastoid surgery and surgery of the parotid region in children particularly challenging. Surgeons operating in children must be extra vigilant to avoid iatrogenic facial palsy.
- The management of facial palsy in children includes treatment for eye exposure, smile asymmetry, drooling and lack of labial function and synkinesis.

CHAPTER 22

EPISTAXIS

Mary-Louise Montague and Nicola E. Starritt

SEARCH STRATEGY AND EVIDENCE BASE

A literature search was conducted for systematic reviews and randomized controlled trials and guidelines with the focus on management of childhood epistaxis. The core search terms used for Medline, Embase, and the Cochrane Database of Systematic Reviews were epistaxis and nosebleeds and were limited to children 0–18 years. The guidelines databases on www.evidence.nhs.uk, NICE Clinical Knowledge Summaries and BestBETS (Best Evidence Topics) were also searched.

INTRODUCTION

Epistaxis, from the Greek *epistazō*, 'to bleed at the nose', is a common problem in children although it is rarely severe and seldom requires hospital admission. Most episodes resolve spontaneously and can be managed at home or in the community setting. Recurrent frequent nosebleeds can, however, cause distress and anxiety to children and their parents and can be disruptive to sleep, school and sporting activities. It is this group of children who are most frequently referred for assessment and treatment to an otolaryngologist along with children presenting with severe acute bleeding and those children in whom an unusual aetiology is suspected.

EPIDEMIOLOGY

There is a bimodal distribution in the incidence of epistaxis, with peaks occurring in children under 10 years and adults over the age of 50 years. In childhood, as in adulthood, it is more common in males than females. It peaks between the ages of 3 and 8 years, and becomes much less common after puberty. Up to 60% of children will have had at least one nosebleed by the age of 10 years.[1] A cross-sectional study of 1218 children aged 11–14 years reported that 9% had frequent episodes of epistaxis.[2] The incidence of recurrent childhood epistaxis is highest in the winter months in northern climates. This mirrors the seasonal increase in viral upper respiratory tract infections and low relative indoor humidity associated with central heating use.[3] The presentation of epistaxis under the age of 2 years is rare and should prompt consideration of either an underlying coagulation disorder or non-accidental injury.[4,5]

ANATOMY

In children anterior bleeds are by far the most common type, accounting for more than 90% of epistaxis.[6] They originate from Little's area on the anterior nasal septum either from Kiesselbach's plexus, a richly vascular arterial anastomosis just under the thin overlying nasal mucosa, or from retrocolumellar veins. Kiesselbach's plexus is formed by the anastomoses of the septal branches of five arteries: anterior and posterior ethmoidal arteries, sphenopalatine artery, greater palatine artery and the superior labial artery. Little's area therefore receives arterial supply from both the external and the internal carotid arteries.

PATHOGENESIS

The precursor to epistaxis in children is most commonly local dryness and crusting over Little's area (**Figure 22.1**).

Figure 22.1 Endoscopic view of nasal septal crusting seen in children with recurrent epistaxis.

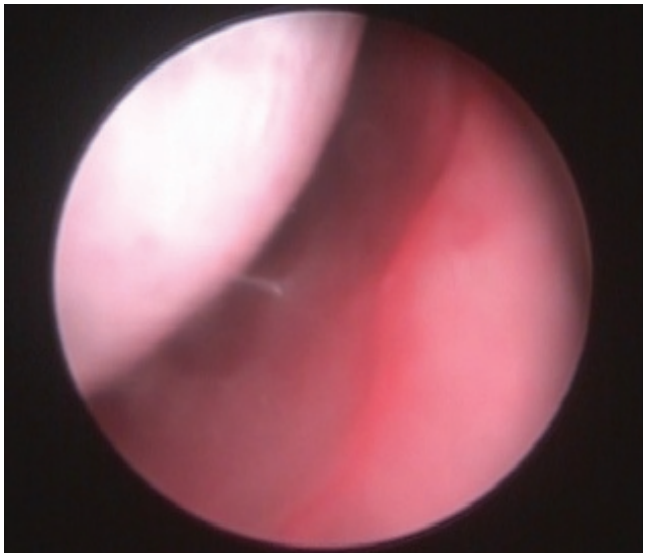

Figure 22.2 Endoscopic view of prominent septal vessels seen in children with recurrent epistaxis.

Most cases were historically labelled as idiopathic but recent evidence has led to the hypothesis that colonization of the nasal cavity by *Staphylococcus aureus* may contribute by causing low-grade inflammation.[7] Release of inflammatory mediators in response to more prolonged inflammation is thought to lead to neovascularization of the nasal septal mucosa. This may give rise to the frequently seen vessels on Little's area (Figure 22.2) which have been shown histologically to be thin-walled arterioles and capillaries with a surrounding inflammatory infiltrate.[8]

AETIOLOGY

Recurrent childhood epistaxis is usually attributed to digital trauma. Other common causes include allergic, viral and bacterial rhinitis and foreign bodies. Table 22.1 illustrates the range of local and systemic aetiologies one needs to consider in children.

TABLE 22.1 Local and systemic aetiologies of epistaxis in children

	Aetiology	Examples
LOCAL	Trauma	Nose picking or rubbing Blunt trauma or facial fractures Foreign body
	Inflammation	Upper respiratory infection Allergic rhinitis Vasculitis
	Anatomical	Septal deviation Septal perforation
	Neoplasms	*Benign* • Polyps • Pyogenic granuloma • Haemangioma • Juvenile nasopharyngeal angiofibroma • Inverted papilloma *Malignant* • Rhabdomyosarcoma • Nasopharyngeal carcinoma • Lymphoma
	Intranasal drugs	Steroids Decongestants Cocaine
SYSTEMIC	Bleeding disorders	*Coagulopathies* • von Willebrand Disease • Haemophilia *Platelet disorders* • Idiopathic thrombocytopenic purpura • Glanzmann thrombasthenia • Bernard–Soulier syndrome *Myeloproliferative disease* • Leukaemia • Thrombocytopenia
	Vascular abnormalities	Hereditary haemorrhagic telangiectasia (Rendu–Osler–Weber syndrome)
	Liver disease	
	Antiplatelet drugs	Aspirin Non-steroidal anti-inflammatory drugs
	Other drugs	Anticoagulants Valproic acid
	Parasitic infection	Dengue haemorrhagic fever

Tumours, such as juvenile nasopharyngeal angiofibroma (JNA) and rhabdomyosarcoma, are rare causes of epistaxis that can be both dramatic and difficult to control. JNA is a benign vascular hormonally sensitive tumour which arises in the lateral nasopharynx and occurs only in adolescent males. Although benign, it can cause severe problems through local invasion of adjacent structures.[9] Rhabdomyosarcoma is a rare malignant tumour occurring in young children presenting with severe intermittent epistaxis. It causes nasal obstruction with or without mucopurulent or bloody nasal discharge, often with signs of Eustachian tube dysfunction such as unilateral middle ear effusion. It can also present with pain and cranial

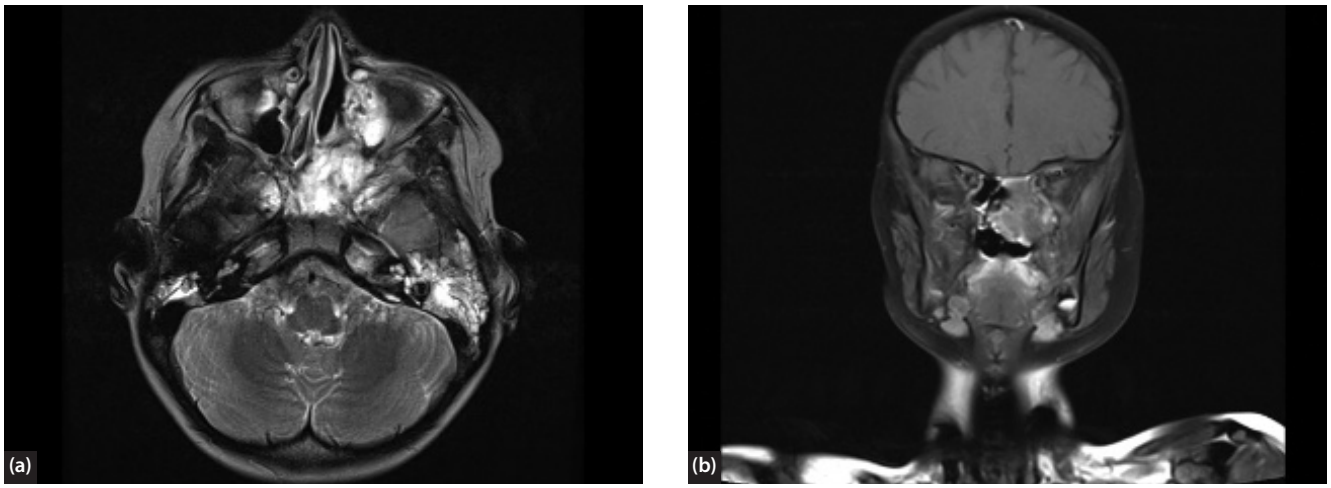

Figure 22.3 (a) Axial MRI and **(b)** coronal MRI showing nasopharyngeal rhabdomyosarcoma displacing the parapharyngeal fat space laterally. Opacification of right middle ear and mastoid air cells is also seen.

neuropathies (**Figure 22.3**). Nasopharyngeal carcinoma is fortunately rare in children. Approximately 50% present with epistaxis. It is often accompanied by a neck mass or neck pain.[10]

Primary and acquired coagulopathies are less common causes of nosebleeds in children but may present with recurrent or extremely refractory epistaxis. Von Willebrand disease (vWD) is the most commonly identified inherited coagulopathy with a prevalence of 5–10% in children with recurrent epistaxis when full coagulation studies including tests for vWD are performed.[2, 11] The haemophilias (factors VII, VIII, IX or XI deficiency) are much less common. Acquired coagulopathies are a rare cause of epistaxis in children in comparison to adults. They include various liver diseases with consequent depletion of clotting factors. An acquired form of vWD has also been described in children receiving valproic acid for epilepsy.[12]

Hereditary haemorrhagic telangiectasia (HHT) (Rendu–Osler–Weber syndrome), an autosomal dominant disorder of blood vessel walls characterized by extensive mucocutaneous telangiectasias, also causes recurrent epistaxis in more than 90% of those affected. Nosebleeds present at a mean age of 12 years and progressively worsen with age.[13] Gastrointestinal bleeding and pulmonary arteriovenous malformations can occasionally occur in childhood.

Nosebleeds often occur in children with thrombocytopenia either secondary to chemotherapy or a haematological disorder. It is rare, however, for haematological disorders to present with epistaxis as the primary symptom in children. Although rare, Glanzmann thrombasthenia, in which the platelet glycoprotein IIb/IIIa complex is either deficient or dysfunctional, is the commonest of the genetic platelet disorders.

ASSESSMENT

The assessment of children with recurrent epistaxis should begin with a careful history and physical examination.

History

The history should include the frequency, duration and laterality of the bleeding. Most epistaxis is bilateral, although one nostril may be more severely affected. One should also enquire about associated nasal and systemic symptoms and any precipitating factors including trauma. Past medical, family and drug histories and review of systems should also be covered.

UNILATERAL NASAL SYMPTOMS

When epistaxis is unilateral and accompanied by foul-smelling nasal discharge in a young child, a foreign body must be presumed present until proven otherwise. Having excluded a nasal foreign body, unilateral epistaxis should raise suspicion of a more serious local cause in the nose such as angiofibroma in a teenage boy or rhabdomyosarcoma in a younger child. Other 'red flag' symptoms include unilateral nasal obstruction, pain and facial swelling.

ALLERGIC RHINITIS

Nasal itch and blockage along with watery rhinorrhoea and sneezing are suggestive of allergic rhinitis.

SYSTEMIC SYMPTOMS

Bleeding from other anatomical sites or a history of easy bruising may indicate an underlying bleeding disorder. Symptoms of fever, arthralgia and weight loss may point to a diagnosis of vasculitis such as Granulomatosis with polyangiitis (Wegener's Granulomatosis), which may manifest in adolescence with epistaxis.

FAMILY HISTORY

A family history of bleeding disorders (e.g. HHT, haemophilia) should be enquired about. Often no definitive condition is identified but a positive family history of prolonged bleeding after surgery or dental extraction may warrant onward referral for haematological investigations.

DRUG HISTORY

Nosebleeds may be more frequent or more difficult to control in children taking certain medications, particularly anti-inflammatory agents (aspirin, ibuprofen) and anticoagulants (e.g. children with complex congenital heart disease or thromboembolic disease). Incorrect application of topical steroid sprays for rhinitis resulting in nasal septal trauma may be complicated by epistaxis.

ALLERGY HISTORY

A history of nut or soya allergy becomes pertinent if prescription of a topical antiseptic cream containing arachis (peanut) oil is being considered. There is a possible relationship between allergy to peanut and allergy to soya and it should not be used in children with soya allergy either.[14]

Clinical examination

Clinical examination focuses on the nose but complete ENT, head and neck and general examination of the child are also required. Younger children feel more secure sitting on a parent's knee. Initial assessment can be made with the child looking upwards by gently elevating the tip of the nose with a thumb allowing inspection of the nasal vestibule, anterior nasal septum, and anterior portion of the inferior turbinate illuminated by a headlight. Anterior rhinoscopy can also be performed with a well-illuminated otoscope with a large speculum.

The most common findings are crusting (two-thirds of children) and visible vessels (40–50% of children) on the anterior septum.[15, 16] Hallmarks of allergic rhinitis may be present including a transverse nasal skin crease ('the allergic salute'), and periorbital markers such as 'allergic shiners' and 'Dennie–Morgan lines'. Pale or bluish nasal mucosa and turbinates are also typical in allergic rhinitis. A nasal foreign body should be excluded. Distortion of nasal anatomy, an intranasal mass, polyps or cervical lymphadenopathy should raise the suspicion of tumour and also prompt a screen for cranial nerve palsies.

Rigid nasendoscopy is not tolerated well by children and, if a more posterior view of the nasal cavity and nasopharynx is required, a fine 2.2 mm flexible nasendoscope can be used after application of topical anaesthetic and vasoconstricting agent. Given the low yield of nasal endoscopy findings in younger children in particular, routine use is probably not warranted.[17] As the diagnosis of a nasal mass is most likely in adolescent males, nasal endoscopy should continue to be routine in their assessment.

Stigmata of systemic causes of bleeding, such as bruising, petechiae, cutaneous or mucocutaneous telangiectasia, should be looked for. Pallor may indicate significant blood loss or anaemia. The jaundiced child may have liver disease with a secondary coagulopathy.

In some circumstances, if an adequate view cannot be obtained or the child is not sufficiently cooperative, examination under general anaesthesia may be required.

INVESTIGATIONS

No consensus exists on the standard laboratory workup for paediatric epistaxis with clinician judgement largely guiding outpatient investigations. The routine use of blood testing is not advantageous from a healthcare cost perspective as there is such a low yield of significant findings.[17] Observational studies suggest that laboratory tests should be considered for children with prolonged (i.e. more than 30 minutes) or severe bleeding despite appropriate application of pressure, in children under the age of 2 years, and when the history and physical findings are suggestive of a bleeding disorder, malignancy, liver or other systemic disease.

Laboratory tests may include a full blood count (FBC) with differential white cell count and platelet count, and a coagulation screen comprising prothrombin time (PT) and activated partial thromboplastin time (APTT). The international normalized ratio (INR) should be checked if the child is receiving anticoagulants. Children found to have abnormalities should be referred for investigation to a paediatric haematologist. Further laboratory tests may include factor assays, von Willebrand factor and platelet function assays.

When tumour is suspected on the basis of history and examination including nasendoscopy, the diagnosis is usually confirmed by contrast-enhanced MRI. CT is often complementary. In the case of JNA a vascular-enhancing nasopharyngeal mass is seen (**Figure 22.4a**,**b**). Intranasal biopsy of JNA, which is a highly vascular tumour, should be avoided because of the risk of life-threatening bleeding. Selective digital subtraction angiography (DSA) elegantly demonstrates the vascular supply and allows pre-operative embolization of feeder vessels (**Figure 22.5a**,**b**). Post-embolization surgical resection is the treatment of choice.

When tumour is suspected, multidisciplinary review and discussion are essential between paediatric otolaryngologist, oncologist and radiologist to ensure that appropriate laboratory tests, imaging and histopathological specimens are obtained.

MANAGEMENT

Epistaxis in children can present either as an acute spontaneous episode or as chronic recurrent intermittent episodes of bleeding. The management of both scenarios is outlined.

Management of acute episodes of bleeding

It is unusual for acute epistaxis in children to need urgent transfer to hospital for resuscitation, most responding to direct pressure over the soft cartilaginous part of the nose (alae nasi) for 10–15 minutes (the Hippocratic method) (**Figure 22.6a**,**b**). Urgent transfer to hospital should be arranged if the bleeding is not responsive to pressure.

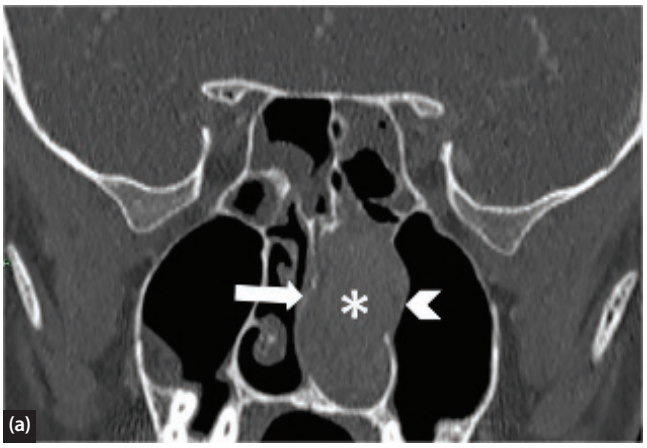

Figure 22.4 (a) Coronal CT. Juvenile nasopharyngeal angiofibroma (asterisk) extending into the choana with obstruction of the left nasopharynx, bowing of the vomer to the right (arrow) and bowing of the medial wall of the left maxillery antrum (arrowhead). **(b)** Axial CT. Initial assessment in the emergency department focuses on the child's airway, breathing and circulation. In a haemodynamically unstable child an effort should be made to assess blood loss, secure intravenous access and send venous blood for FBC, coagulation screen and blood group and save followed by fluid resuscitation. If the child is haemodynamically stable at presentation, laboratory blood tests do not need to be requested routinely. A careful history is taken from the parent or carer. The nasal cavity is examined, gently looking for a bleeding point anteriorly.

If the bleeding stops with first aid measures, a topical antiseptic cream (e.g. containing chlorhexidine hydrochloride 0.1% and neomycin sulfate 0.5%) can be applied and continued twice daily for up to 2 weeks to minimize crusting. If there is a history of peanut, neomycin or soya allergy, mupiricin ointment can be prescribed twice daily for 1 week as an alternative. Most acute nosebleeds in children respond to simple pressure and do not require referral to otolaryngology services.

Examination of the child who continues to bleed despite nasal pressure can be difficult. The oropharynx should be inspected for signs of posterior bleeding. Subsequent measures to control anterior epistaxis include nose blowing followed by gently placing cotton pledgets soaked in vasoconstrictor and local anaesthetic such as Co-phenylcaine

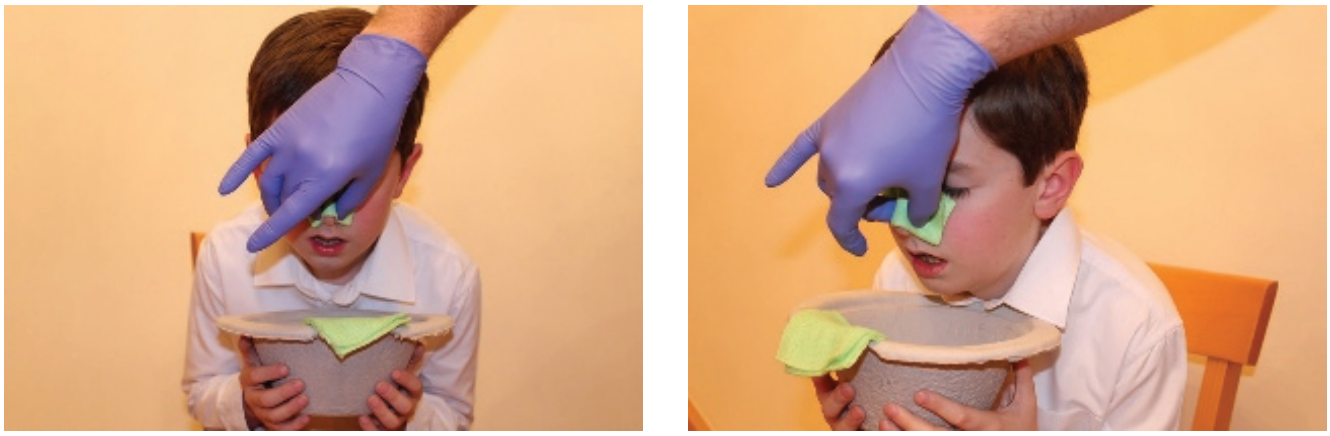

Figure 22.6 Demonstration of Hippocratic method to arrest bleeding with child seated, head tilted slightly forward and mouth open to prevent airway obstruction and swallowing of blood.

(lignocaine hydrochloride 5% with phenylephrine hydrochloride 0.5%) or Oxymetazoline in the anterior nasal cavity. This is followed by further digital pressure for 5 minutes. In small children the lowest concentration of phenylephrine should be used (e.g. phenylephrine 0.25% diluted with an equal volume of sterile saline to 0.125%).

If bleeding continues the next step is usually chemical cautery with silver nitrate if a bleeding point can be seen anteriorly and the child can tolerate the procedure. Using a stick, 75% silver nitrate is applied to the bleeding point for up to 5 seconds (Figure 22.7) until a grey-white eschar develops (Figure 22.8a,b). Excess chemical should be gently mopped away with a cotton bud, topical antiseptic applied to the site and a barrier lubricant such as soft white paraffin applied to the external skin to protect it. The topical antiseptic preparation is continued twice daily for up to 2 weeks. Local chemical cautery is sufficient to control most epistaxis in children.

The placement of an anterior nasal pack under direct vision may be required if the bleeding continues despite local cautery, in the presence of diffuse mucosal bleeding or in a child with a coagulopathy pending treatment directed at rectifying the bleeding problem. Absorbable packs such as gelatin sponge, alginate or oxidized cellulose are favoured in children over non-absorbable packs, having the obvious advantage of not requiring subsequent removal, which in itself may cause further trauma to the anterior nasal septum (Figure 22.9). If an anterior pack is placed, the child should be admitted to the ENT or children's ward for observation.

Examination under anaesthesia may be required if bleeding continues, or in a young child unable to tolerate

Figure 22.7 Stick with 75% silver nitrate used for chemical cautery.

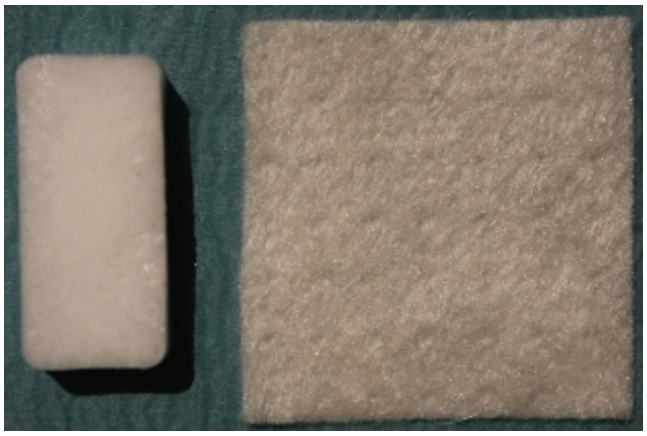

Figure 22.9 Gelatin sponge pack (left) and Alginate packing material (right).

chemical cautery or placement of an anterior pack under local anaesthesia. Chemical cautery or electrocautery can be undertaken with or without placement of an anterior pack.

Posterior bleeding in children is much less common but often more severe and should be suspected if the bleeding is profuse and bilateral, there has been no response to pressure and a bleeding site cannot be identified anteriorly. Rarely, placement of a posterior nasal pack or balloon inflated under general anaesthesia is warranted. Thorough examination of the nasal cavity and nasopharynx can be performed simultaneously. The child should be cared for post-operatively on the critical care floor until the post-nasal pack or balloon is removed, again usually under general anaesthesia.

The child with persistent anterior or posterior epistaxis refractory to these measures in the absence of a correctable bleeding disorder may require consideration of either arterial ligation or radiological selective arterial embolization. These are rarely necessary in children.

Management of recurrent episodes of bleeding

In children referred to the otolaryngologist for outpatient assessment and treatment of recurrent epistaxis a detailed history and examination should seek to determine if there is an underlying cause. It should also be established what treatment, if any, has already been provided in the primary care setting.

If the child is not at high risk of having a serious underlying cause for their recurrent epistaxis, treatment options should be discussed and include:

- mucosal hydration with saline drops or spray
- emollients, e.g. petroleum jelly
- topical antiseptic cream
- chemical cautery
- chemical cautery combined with antiseptic cream
- bipolar electrocautery.

The optimal management of recurrent epistaxis in children remains controversial as the available studies are limited by small numbers and short-term follow-up.[18] Petroleum jelly application to the nose is often recommended but it has no benefit over simple observation.[16] Topical antiseptic cream was found to significantly increase the resolution of recurrent epistaxis at 8 weeks when compared to no treatment.[15] Long-term benefit of topical antiseptic, however, has not been established.[19] It is not known if chemical cautery is better than no treatment but, if a child has been referred to a paediatric otolaryngology clinic and has already had treatment with an antiseptic cream, most would consider it reasonable to offer chemical cautery if a prominent vessel is visible as it is of low morbidity. Antiseptic cream would appear to be as effective as silver nitrate cautery in reducing the number of nosebleeds in children with recurrent epistaxis.[20, 21] It is therefore not unreasonable for antiseptic cream to be considered the first-line treatment for recurrent epistaxis in children in primary care. Treatment with chemical cautery and antiseptic cream may be more effective than antiseptic cream alone at 4 weeks after completing treatment in children with visible anterior septal vessels.[22]

It is recommended to use 75% rather than 95% silver nitrate for chemical cautery in children as it appears to be more effective, has fewer side effects and is less painful.[23] Simultaneous bilateral cautery is not recommended owing to the possible increased risk of septal perforation.[24]

Bipolar electrocautery may be superior to chemical cautery under general anaesthesia in children who will not tolerate outpatient chemical cautery. It has been shown to afford a longer epistaxis-free period and a lower incidence of recurrence within 2 years of treatment. After 2 years however, the outcomes of the two treatments are no different.[25]

Less commonly performed interventions in children include laser treatment, submucosal resection or limited septoplasty in the presence of septal deviation or a prominent septal spur and endoscopic diathermy but these are usually only applicable on an individual case basis and are not supported by a strong evidence base.

The management of HHT in children requires special mention as it may require unique approaches to treatment. Chemical cautery should be avoided and, when packing is necessary, absorbable packing is preferred. Treatment with topical fibrin glue or matrix sealant (e.g. Floseal), the anti-fibrinolytic agent, tranexamic acid, KTP laser, cold ablation and the anti-neoplastic agent Bevacizumab (Avastin) have been employed in some centres with some success though there is very little in the published literature with respect to their use, safety and efficacy in children. Septal dermoplasty remains a viable surgical option but has the disadvantage of a donor split skin graft site and associated discomfort for the child.

Prevention of further bleeds

After treatment for either acute or recurrent epistaxis, parents/caregivers should be educated in the correct first-aid management in the event of recurrence. Children's fingernails should be kept trimmed and clean. Management of suspected or proven allergic rhinitis is

essential to help prevent recurrence. Parents should be instructed how to apply their child's nasal steroid spray correctly, with advice to hold the bottle in the opposite hand (right hand for left nostril and vice versa) to ensure the spray is directed to the lateral nasal wall and away from the septum.

BEST CLINICAL PRACTICE

- ✓ In acute epistaxis the child's airway, breathing and circulation should be assessed and, if compromised, urgent transfer arranged to the emergency department.
- ✓ Adolescent boys with unexplained recurrent epistaxis require urgent referral to otolaryngology as JNA is possible, although rare.
- ✓ In children younger than 2 years of age consider referral to a paediatrician with child protection expertise as epistaxis is unusual in this age group.
- ✓ Laboratory investigations are not usually required unless an underlying cause for recurrent epistaxis is suspected.
- ✓ Chemical cautery with 75% silver nitrate in the hands of an appropriately trained clinician is a well-tolerated procedure with little morbidity and should be offered when there is a visible blood vessel.
- ✓ Antiseptic cream containing peanut oil must not be prescribed for children with known or suspected peanut allergy.

FUTURE RESEARCH

- ➤ It is unlikely that the role of silver nitrate cautery will ever be validated by randomized controlled trials as this treatment is operator-dependent.
- ➤ There is a lack of study data assessing the effect of recurrent epistaxis on the quality of life of the child and parent or the effect of intervention on quality of life indices.
- ➤ High-quality studies, with longer follow-up, are needed to ascertain which, if any, of the current treatments for recurrent epistaxis in children are optimal in its long-term prevention.
- ➤ As most epistaxis in children is managed in the primary care setting, large population studies on the natural history of epistaxis and the effect of intervention will need to be primary-care centred.

KEY POINTS

- Epistaxis in children is extremely common and usually innocuous.
- The most common cause of epistaxis in the paediatric population is digital trauma.
- Most episodes of acute epistaxis in children respond to simple compression and do not require hospital referral.
- Routine laboratory blood testing is not indicated for most children with self-limiting epistaxis.
- Spontaneous resolution of benign simple recurrent epistaxis in children is to be expected.

CHAPTER 23

NEONATAL NASAL OBSTRUCTION

Michelle Wyatt

SEARCH STRATEGY

Data in this chapter may be updated by a Medline search using the keys nasal obstruction and neonatal and focusing on a variety of keywords appropriate to the individual topics. These include all the subheadings listed below (e.g. choanal atresia, piriform aperture stenosis). The Cochrane Database of Systematic Reviews and the National Electronic Library for Health for ENT were also consulted.

INTRODUCTION

The aetiology of neonatal nasal obstruction is diverse. Neonates are generally obligate nasal breathers for the first few months of life, and therefore they can present as acute respiratory emergencies, classically with cyclical cyanosis, relieved by crying. The extent of their problems will alter related to the neonate's ability to breathe orally which is dependent on their maturity and neurological development. Thus, an oral airway is often sufficient to relieve the respiratory distress until definitive treatment can be undertaken.

Neonates with nasal obstruction may also present with stertor and feeding problems. Failure to thrive particularly raises level of concern. Examination is essential.

BOX 23.1 Congenital causes of nasal obstruction in neonates

Anatomical/ skeletal anomalies	Congenital nasal cysts	Nasal masses
Choanal atresia	Dermoid cysts	Glial heterotopia
Pyriform aperture stenosis	Nasolacrimal duct cysts	Meningo- or encephalocoele
Midnasal stenosis	Thornwald's cyst	Haemangioma
Nasal agenesis	Nasoalveolar cysts	Teratoma
Craniosynostosis syndromes	Dentigerous cysts	Hamartoma
'Cleft palate' nose	Mucous cysts	Chordoma

BOX 23.2 Acquired causes of nasal obstruction in neonates

Structural	Inflammatory
Osseocartilaginous nasal deformity	Neonatal rhinitis

Flexible nasendoscopy is particularly useful and imaging via computed tomography (CT) and magnetic resonance imaging (MRI) is of great value in delineating both nasal and post-nasal lesions.[1, 2]

Boxes 23.1 and 23.2 list the variety of causes of neonatal nasal obstruction. This chapter aims to review those conditions not covered elsewhere in this book.

CONGENITAL DISORDERS

Skeletal anomalies

CHOANAL ATRESIA

This is a rare condition (incidence 1 in 7000 live births) in which there is complete obstruction of the posterior choanae on one or both sides (Figure 23.1). The blockage is thought to be either bony or membranous in origin, but in reality a mixed picture is usually seen (70% of cases), with the remainder being purely bony. It is believed to be secondary to persistence of the nasobuccal membrane.

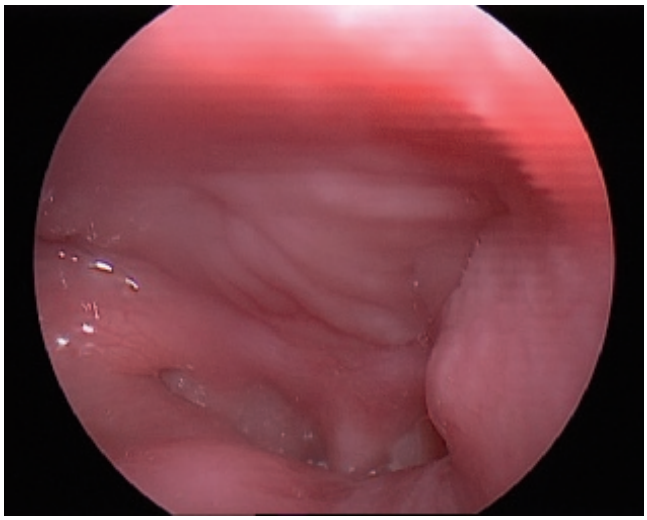

Figure 23.1 Bilateral choanal atresia as viewed from the nasopharynx with a 120-degree endoscope.

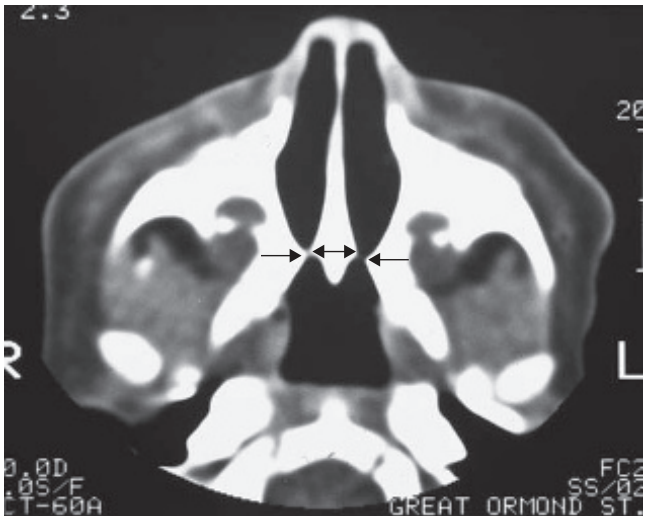

Figure 23.2 CT scan (axial view) to illustrate the expansion of the posterior vomer and medial maxillary walls of the nasopharynx in choanal atresia (arrows).

Bilateral choanal atresia in neonates presents as acute respiratory distress as neonates are obligate nasal breathers. Classically the neonate will have cyclical cyanosis relieved by crying, and placement of an appropriate-sized oral airway resolves the distress. Unilateral choanal atresia may present later in life, and can be picked up in neonates when there is an inability to pass a nasogastric tube through one nasal passageway.

Neonates with choanal atresia will have difficulty with feeding. The uvula and epiglottis usually form a respiratory channel from the nose to the larynx with two lateral pathways from the mouth to the oesophagus to allow for the safe passage of food. In neonates with bilateral choanal atresia this respiratory channel is lost and therefore cyanosis can develop during feeds.[1] McGovern nipples have been shown to be of benefit for children who develop feeding difficulties.

Misting upon placement of a metal spatula below the neonate's external nasal aperture excludes a diagnosis of choanal atresia, and this test can easily be performed in the clinic setting. If suspected, the diagnosis should be confirmed with flexible nasendoscopy, and CT scanning should then be performed to determine the extent and nature of the choanal atresia (with suction clearance of the nose and application of 0.5% ephedrine drops 30 minutes prior to scanning) (**Figure 23.2**). In neonates, often a simple oral airway is well tolerated, in which case endotracheal intubation can be avoided.

Choanal atresia can occur in isolation, but it can also be one feature of a number of associated congenital anomalies in the CHARGE (coloboma, **h**eart defects, **a**tresia choanae, **r**etardation of growth, **g**enital anomalies, **e**ar abnormalities) syndrome, due to mutations in the *CHD7* gene on chromosome 8. These abnormalities must be excluded in a child with choanal atresia and therefore the minimum investigations in addition to the nasal CT scan are cardiac echo, renal ultrasound scan, and an ophthalmology and audiology review.

The literature describes numerous techniques for the repair of choanal atresia, but there is little in the way of direct comparisons and outcomes are difficult to define objectively. Most studies report on the surgeons' assessment of the size of the nasal airway, and whether the family feel that the symptoms have resolved. The number of surgeries required and time taken to reach a satisfactory outcome are used to make comparisons. A recent Cochrane review concludes that there is no definitive evidence to demonstrate the potential advantages or disadvantages of any surgical technique for patients with choanal atresia.[3]

The two most common techniques for choanal atresia repair are the transnasal and transpalatal approaches, but the sublabial, transantral and transseptal approaches have also been described.[4] Transpalatal and transnasal surgery have been shown to have similar outcomes.[5] The transpalatal technique is not as common now, but it can be useful in those neonates with significant craniofacial anomalies where the dimensions of the nose and postnasal space are limited.

There are two methods described for the endoscopic transnasal approach. One involves using the zero degree endoscope transnasally, with serial dilatations using urethral sounds or using powered instruments such as microdrills. In cases where the nasal cavity is too small to accommodate both instruments a posterior septal window is created and expanded, thus allowing the endoscope through one nostril and the powered instrument through the other nostril, creating a 'neo-unichoana'.[6, 7]

The second transnasal approach involves a 120-degree endoscope being placed in the mouth and positioned in the nasopharynx behind the soft palate to give a view of the postnasal space. Instruments and the drill can then be introduced through the nose. This technique is described in three papers from Great Ormond Street Hospital in London and represents the largest reported experience at 161 patients using the endoscopic transnasal approach.[8–10]

Figure 23.3 Bilateral nasal stents with an endotracheal tube bridging piece.

There are reports in the literature of high success rates using the endoscopic endonasal approach with balloon dilatation for choanal atresia, although the numbers involved in these series are still quite small.[11]

The role of nasal stenting post choanal atresia repair is also debated. If used, bilateral nasal stents can be fashioned from two ivory Portex™ endotracheal tubes cut to length with the bevelled end of each sitting in the nasopharynx orientated towards the septum. The philtrum is protected by either a small length of size 12 suction catheter cut to act as a bridging piece or a further small piece of endotracheal tube (**Figure 23.3**). The stents are secured by a circumseptal '0' prolene suture and left *in situ* for up to 6 weeks. An alternative is to use a single tube as a stent, with a window cut in the middle to allow access for the securing suture. This avoids the need for a bridging piece (**Figure 23.4**). There is debate as to the need for stenting, and a systematic review with meta-analysis has shown that the success rates for bilateral choanal atresia repair are similar with and without nasal stents, and that the use of stents may be associated with more complications.[12]

There is evidence that regular suctioning to clear secretions and daily washing with sodium chloride solution results in successful outcomes.[13] Authors who do not support using stents stress the need for resection of the posterior aspect of the vomer and early (1 week post repair) repeat examination for removal of granulations and dilatation as required.[13]

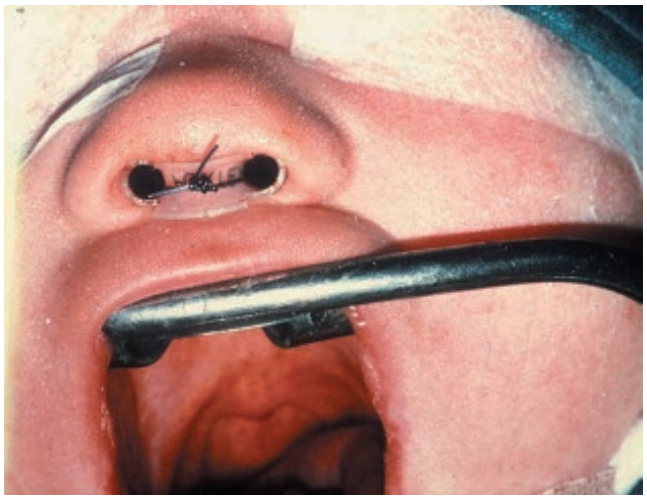

Figure 23.4 Bilateral nasal stents without a bridging piece.

Given the limitations in the definition of outcome as described previously, success rates have been shown to be similar over the past 20 years with the three Great Ormond Street papers showing rates of 68–80% for bilateral and 82–93% for unilateral choanal atresia. A group of 78 children from the Philadelphia Children's Hospital were followed up for 35 months on average with similar results.[14]

Mitomycin C is thought to act to reduce granulation tissue and fibrosis by inhibiting fibroblasts and angiogenesis leading to its use during stent removal. However, several papers have found no benefit in terms of outcomes whether mitomycin C is used or not.[12, 15] Carter et al. suggest, however, that mitomycin does have beneficial effects.[16] The KTP laser has also been shown to be helpful in the treatment of granulation tissue which develops post-operatively.[5]

PIRIFORM APERTURE STENOSIS

This abnormality, first described in 1988, is a very rare condition leading to nasal obstruction in the neonate which arises due to bony overgrowth of the nasal process of the maxilla (**Figure 23.5**).[17] The piriform aperture is the narrowest part of the nasal airway and so even minimal reduction in diameter here can cause significant problems. Symptoms similar to bilateral choanal atresia occur and epiphora is also often seen secondary to bony involvement of the nasolacrimal ducts. Diagnosis is suggested by the inability to pass a narrow gauge nasogastric tube or 2.2 mm endoscope through the anterior nasal vestibule due to the bony obstruction. CT scan confirms the diagnosis with an aperture width of less than 11 mm measured on an axial CT at the level of the inferior meatus (in a term neonate). CT can also demonstrate a single central incisor, which exists in some affected individuals. This single central incisor is associated with an absent upper frenulum and arch-shaped lower lip. In this subgroup with a 'megaincisor' there is a suggested association with holoprosencepaly, a rare condition in which the developing forebrain fails to divide appropriately to form the cerebral hemispheres, diencephalon, and optic and olfactory bulbs. These patients should undergo further evaluation for central nervous system defects with an MRI and particularly the hypothalamic–pituitary–thyroid axis. There are variable reports on the incidence rates of this condition with piriform aperture stenosis, but a figure of around 50% is generally accepted.[18]

Conservative treatment with nasal steroid drops or decongestants (for up to 2 weeks) and saline irrigation is generally recommended as first-line treatment.[19] If there is severe obstruction, respiratory distress or failure to thrive, surgical treatment is warranted. It has also been found that an aperture of less than 5 mm on CT is almost always associated with the need for surgical intervention.[20]

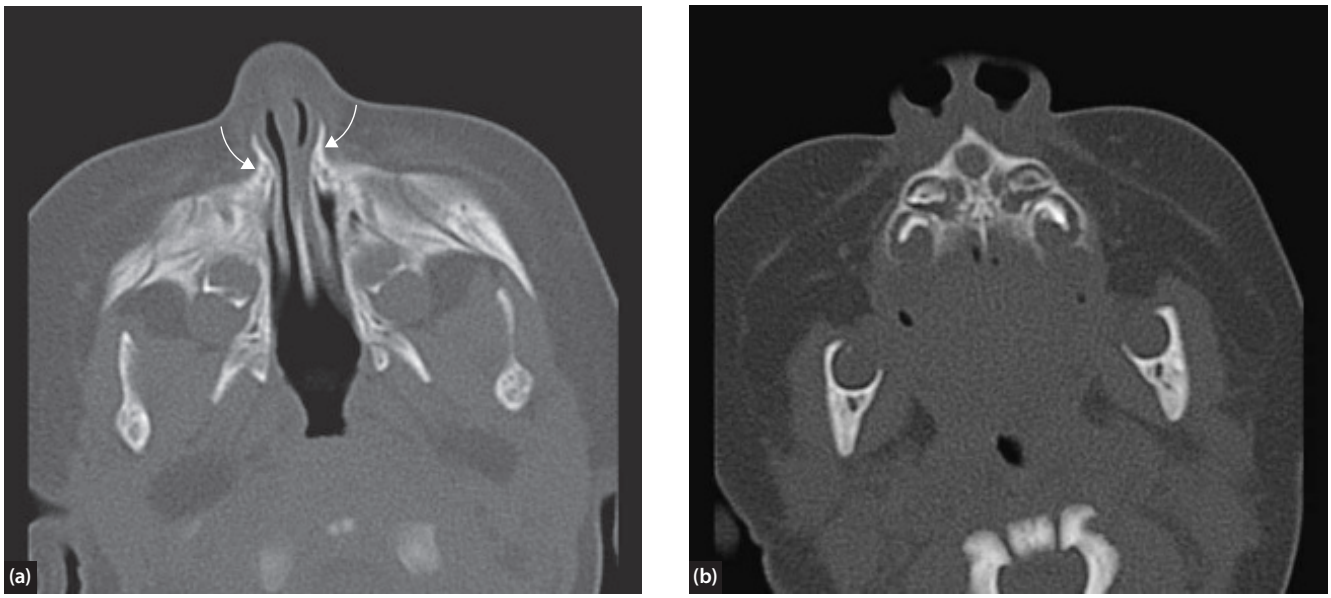

Figure 23.5 CT scan (axial view) of bilateral piriform aperture stenosis. Note the single central incisor.

Surgery involves either a transnasal approach with an alar-releasing incision or a sublabial approach with a gingival–buccal sulcus incision and elevation of the soft tissue and periosteum to expose the piriform aperture. The abnormal bone is drilled away using a diamond burr and the mucoperiosteal flap replaced. Post-operatively nasal stents can be used for up to 4 weeks, although more recent studies suggest that stenting is not necessary.[21] Complications include adhesions, septal perforations and septal ulceration, but the use of suctioning, nasal irrigation and treating gastro-oesophageal reflux minimizes this.[22]

MIDNASAL STENOSIS

Midnasal stenosis is a rare condition secondary to overgrowth of the nasal bones halfway along the nasal cavity. It usually occurs in association with syndromes characterized by midfacial hypoplasia, such as Apert syndrome, but cases in isolation are also reported.[23] Neonates will present in a similar fashion to those with piriform aperture stenosis or choanal atresia with apnoea, cyanosis and failure to thrive. Diagnosis can be confirmed with nasal endoscopy or CT scanning which will demonstrate isolated bony narrowing of the midpart of the nasal cavity or narrowing with stenosis of the rest of the nasal cavity (**Figure 23.6**). Treatment is usually conservative, allowing the child's midface to grow, such that by the age of 6 months the obstruction is relieved. For those children struggling with significant respiratory problems or failure to thrive, dilatations or stent placement can be considered.[1]

NASAL AGENESIS

Complete arhinia is very rare but can occur in isolation or as part of a syndrome. It originates at the fifth week *in utero* when the nasal placode fails to canalize to form the nasal passages. Presentation at birth with acute respiratory distress occurs. Management is initially with an oral airway and tube feeding. A tracheostomy may be required. Definitive surgical treatment usually involves a two-staged procedure aimed at reconstructing the nasal cavity as well as the external nose, and is usually delayed until facial development is almost complete.[24]

Figure 23.6 Midnasal stenosis associated with a patient with Apert syndrome.

Congenital nasal cysts

Congenital cysts, as listed in **Table 23.1**, can either obstruct the nose or cause discharge from an associated sinus tract.

Figure 23.7 Midline nasal sinus associated with an underlying dermoid cyst.

DERMOID CYST

Dermoid cysts (**Figure 23.7**) arise from the ectoderm and mesoderm and usually contain all the structures of normal skin. They are the most common midline nasal mass, and account for between 1% and 3% of all dermoids.

These cysts usually present as a slowly growing cystic midline mass over the nasal dorsum. An associated pit is often seen in any position from the nasal tip to the glabella, and hair may be present at its opening. Occasionally these dermoids can become infected and thus present as an abscess requiring drainage.

Between 4% and 45% of dermoid cysts have an intracranial component, thus pre-operative imaging with CT (for bony anatomy) and MRI (to delineate any connection to the central nervous system) is essential.[25]

Nasal dermoids are discussed in more detail in Chapter 41, Cysts and sinuses of the head and neck.

NASOLACRIMAL DUCT CYST (DACRYOCYSTOCOELE)

The nasolacrimal duct system should canalize *in utero* from a superior to inferior direction and is usually complete by the sixth foetal month through a process of reabsorption; however, not infrequently, at birth the lower end can remain closed. This barrier can be combined with a proximal valve-like obstruction at the junction of the common canaliculus and lacrimal sac, thus the tear fluid builds up resulting in a cyst. This is a common problem for neonates and it is reported that 5–30% of babies are born with nasolacrimal duct blockage.[26] These lesions can cause epiphora and nasal obstruction, sometimes leading to respiratory distress and feeding difficulties, and may present with a bluish cystic mass at the medial canthus. They are more commonly unilateral but can be bilateral,[27] and their incidence is slightly higher in female infants. CT imaging confirms the diagnosis and shows a dilated nasolacrimal duct, an intranasal cyst and cystic dilatation of the lacrimal sac.

Initial management is with nasal decongestants but, if surgical removal is required, endonasal marsupialization under endoscopic guidance is recommended.[27] Endonasal ablation with the carbon dioxide laser has also been reported previously.[26] Opthalmology input is helpful as intra-operative nasolacrimal probing and stenting may be necessary (see Chapter 25, Lacrimal disorders in children).

THORNWALDT CYST

The pharyngeal recess or bursa sits in the midline of the posterior wall of the nasopharynx. It ends next to the adenoids and is lined by the pharyngeal mucous membrane. Cystic transformation of this recess was first described by Thornwaldt in 1885 and so it bears his name. Inflammation of the lesion causes nasal obstruction, occipital pain, fullness in the ears and discharge. It rarely causes significant obstruction in neonates.

Endoscopic examination confirms the diagnosis. Imaging by CT and MRI demonstrates any adhesion to the cervical vertebrae. Incision and excision of the cyst have been described while total clearance requires a palatal approach.[28]

NASOALVEOLAR CYSTS

These are rare, non-odontogenic, soft-tissue lesions arising from the incisive canal during the development of the maxilla. They present lateral to the midline at the alar base and can cause asymmetrical alar flare. Excision is usually via a sub-labial approach, but the transnasal approach has been recently reported.[29]

DENTIGEROUS CYSTS

Dentigerous cysts present in the floor of the nose or maxillary sinus and have a dental origin. Endoscopic marsupialization or removal via the nose is usually satisfactory.

MUCOUS CYSTS

Mucous cysts have been described anywhere in the nose but appear to be more common in the floor. They may be congenital but are more usually seen as a complication of rhinoplasty. Endoscopic and open approaches are used depending on the position of the lesion.[30]

Nasal masses

ENCEPHALOCOELE, MENINGOCOELE, GLIOMA

A nasal encephalomeningocoele represents a herniation of meninges with or without associated brain through bony defects of the calvarium. A meningocoele consists of either

Figure 23.8 Broadened nasal dorsum in a child with a glioma.

meninges alone or with CSF and an encephalocoele contains nervous tissue. Their combined incidence is around 1 in 4000 live births and they have an equal male/female distribution. Encephalocoeles can be described as frontoethmoidal or basal.[31] Frontoethmoidal are usually associated with craniofacial deformity as they arise either at or anterior to the foramen caecum. The basal types present intranasally through defects in the skull base causing nasal obstruction and widening of the nasal bridge.

Nasal gliomas (**Figure 23.8**) are benign midline masses containing glial cells and fibrous and vascular tissue. They are similar to encephalocoeles but have become separated from the intracranial structures. Around 15% do, however, remain attached to the brain via a fibrous stalk. There is usually no associated abnormality of the brain. A better term for these lesions is 'glial heterotopia': glioma implies a neoplasm and these lesions are actually choristomas (aggregations of structurally normal tissue in an abnormal location). Presentation is usually early on as a firm, non-compressible, reddish swelling.

Differentiation between gliomas and encephalocoeles can be made in a number of ways. A probe will pass laterally but not medially to an intranasal encephalocoele while an intranasal glioma can arise from the lateral nasal wall. Furstenberg's test (compression of the internal jugular vein) usually causes an encephalocoele to enlarge but a glioma does not. Imaging is mandatory to confirm the nature of the lesion. MRI is the most effective modality due to its better resolution of soft tissue, and because the anterior skull base contains unossified cartilage which can be mistaken for bony dehiscence on CT, but CT has a role in image guidance. On MRI, an encephaocoele is seen as a mass in continuity with the brain with an associated skull base defect, while a glioma is discontinuous to the brain parenchyma and the tissue is dysplastic and gliotic, therefore more hyperintense on T2 compared to normal brain parenchyma.

Surgical excision is recommended for these masses, particularly if they are causing significant problems. As with dermoid cysts, masses in the lower part of the nose can be removed via the external rhinoplasty approach.[32] More recently, the endoscopic approach is advocated, and this has been shown to have successful outcomes with image guidance.[33, 34] The glial tissue can be removed with a zero-degree or 120-degree endoscope.

Encephalocoeles and meningocoeles that require surgery usually require a combined transnasal and neurosurgical approach. Ventriculoperitoneal shunting may be required pre-operatively. The intracranial portion can be excised via a bicoronal flap with a frontal craniotomy, but this can be associated with complications of epilepsy, anosmia, scarring and intracerebral haemorrhage. More recently, the endoscopic approach is advocated without the need for formal craniotomy.[35] The defect left by endoscopic excision can be closed with temporalis fascia graft, mucosa or a composite graft from the inferior turbinate, with Gelfoam® and packing (if small), or if a larger defect is present fascia lata and bone from the septum may be required. This prevents the risk of CSF leak potentially leading to meningitis. The role of prophylactic antibiotics is controversial.

NASAL HAEMANGIOMA

Vascular anomalies such as haemangiomas, arteriovenous malformations (AVMs) or vascular malformation (including lymphatic malformations) can present in the nose either externally or internally (**Figure 23.9**). Internal haemangiomas often arise from the inferior turbinate.

Classically, a haemangioma is either absent or flat at birth and then undergoes a period of rapid growth to present as a mass at around 6 weeks of age. Growth then continues for the first 6 months of life before gradual involution occurs, and the lesion generally disappears by around the age of 6 years. This natural history supports conservative management if possible. Ultrasound and MRI imaging are the recommended modes of imaging, particularly to exclude any intracranial connection, and treatment depends on the extent of involvement of the surrounding tissues.

Treatment for haemangiomas has been transformed with the use of oral propranolol and involvement of the appropriate paediatric medical team familiar with its use is recommended.[36, 37] In cases where there is encroachment on the orbit with a potential risk to vision, surgical excision has been used to good effect. The use of chemotherapy (such as methotrexate or vincristine) is reported but should be undertaken with caution due to the risks of side effects, and it has now largely been superseded by propranolol (see Chapter 42, Haemangiomas and vascular malformations).[38]

TERATOMA

A teratoma is a true neoplasm consisting of all three germ cell layers with cells varying in maturity. They occur in 1 in 4000 live births with less than 10% occurring in the

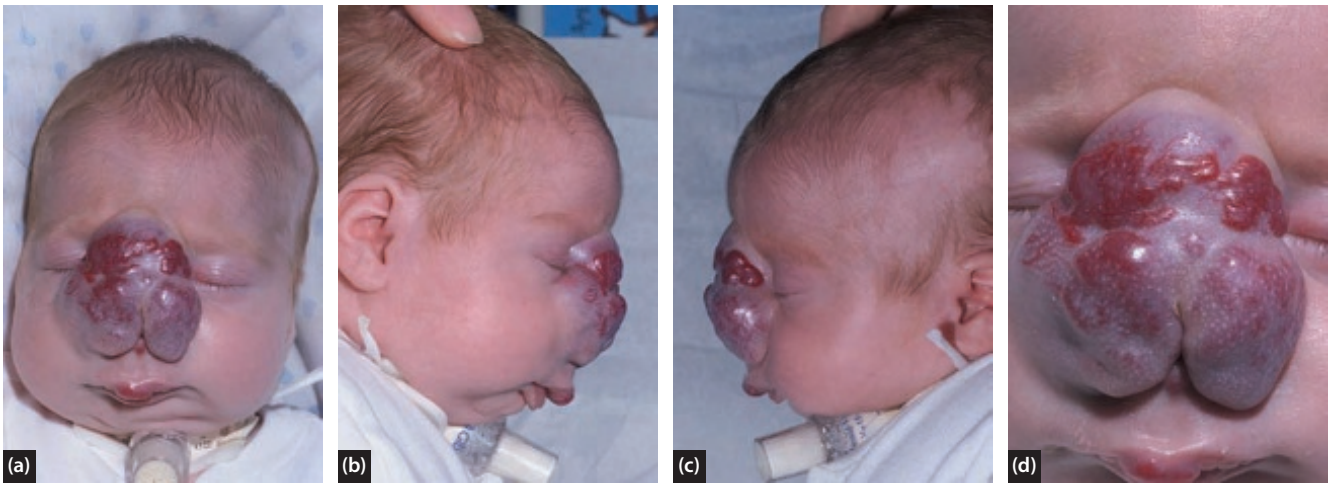

Figure 23.9 External nasal haemangioma in a 10-month-old girl.

head and neck. The cervical forms are the most common, followed by nasopharyngeal teratomas. They are associated with polyhydramnios, stillbirth and prematurity, and can result in significant airway compromise. They usually present as a firm mass.

Maternal serum alpha fetoprotein levels and beta HCG levels may be raised. Imaging is with CT and MRI. Teratomas will appear as heterogeneous masses on MRI, with fatty and bony components, and they may have a stalk, giving them mobility in different positions. Management is surgical, either endoscopic or open, depending on the size of the lesion.[39]

MISCELLANEOUS

Hamartomas, chordomas and craniopharyngiomas are extremely rare causes of nasal obstruction in the neonate.

ACQUIRED PATHOLOGIES

Osseocartilaginous septal deformity

The septum develops as an outgrowth from the merged medial nasal processes and nasofrontal process. At week 9, it fuses with the palate just posterior to the incisive foramen, and then fuses anteriorly and posteriorly.[40] A number of babies are born with a septal deviation either in isolation or in association with an abnormality of the bony pyramid. It is felt that the problem is due either to intrauterine positioning or to birth trauma. Closed reduction of the septal deformity with topical anaesthetic in each nostril in the first few days of life has been described and is thought to be successful if the deviation is severe.[41] However, most of the studies that advocate intervention have inadequate follow-up periods and there is little evidence for the adverse effects of conservative management.[42] Formal surgical repair is generally recommended later in childhood to avoid damage to the main growth centre of the nose; it is interesting, however, that the external rhinoplasty approach has been used for other pathology in very young children and no detrimental effects on nasal growth have been reported (see Vol 1, Chapter 103, Nasal septum and nasal valve).

Neonatal rhinitis

Swelling of the nasal mucosa in newborn infants can cause significant airway problems, particularly when feeding, as neonates are obligate nasal breathers. Idiopathic neonatal rhinitis is characterized by mucoid rhinorrhoea with nasal mucosal oedema in the afebrile newborn. This results in stertor, poor feeding and respiratory distress.[43] Structural abnormalities should be excluded. Treatment of neonatal rhinitis depends on the severity of symptoms. Nasal bulb suction with saline drops in the first instance is recommended. A short course of nasal steroid drops would be the next step. This should be closely monitored to avoid the potential side effects from systemic absorption.

It is important to consider chlamydia infection acquired in the birth canal. This usually results in conjunctivitis but involvement of the nose is seen in around 25% of affected individuals. Presentation is with obstruction, rhinorrhoea and a markedly erythematous nasal mucosa on examination. Swabs are diagnostic and the appropriate antibiotics should be given.

Rarely congenital syphilis (*Treponema pallidum*) can cause nasal symptoms in the neonate. Thin, clear secretions are seen between the second week and third month of life. This progresses to a mucopurulent discharge with significant obstruction and crusting of the nostrils. Antibiotic treatment is required both for symptomatic relief and to prevent chronic infection of the cartilage resulting in saddle deformity.

Fibrous dysplasia

This is an uncommon cause of nasal obstruction in older children and young adults. It is a benign fibro-osseous dysplasia and can present either as a solitary lesion (monostotic) or less commonly in multiple sites (polyostotic), typically in the craniofacial bones. Presentation is usually as pain with progressive facial deformity between the ages of 10 and 30.[44]

Nasal obstruction, with a mass on endoscopy or facial deformity due to growth of a lesion in the nose or sinus should raise suspicion. Imaging helps to confirm the diagnosis; normal healthy bone is replaced with a more radiolucent 'ground-glass' appearance. There can be endosteal scalloping of the inner cortex with a smooth non-reactive periosteal surface. Lesions have diffuse margins.

Management is expectant but surgical excision may be needed with the aim of preserving function and limiting disability. The mid-facial degloving approach has been shown to achieve good results with minimal cosmetic defect.

Medical treatment involves medication to increase bone density, for example biphosphonates.

A subgroup of polyostotic patients (around 3%) have associated endocrine abnormalities such as hyperthyroidism, adrenal disorders, diabetes, hyperpituitarism and hypercalcaemia with cafe-au-lait spots. This is termed McCune–Albright syndrome after the two physicians who first described it in 1937.

The condition usually becomes dormant by adulthood but there is a 1% risk of malignant transformation, mostly in the polyostotic form.

Neoplasms of the nasal bones

Juvenile ossifying fibroma (JOF) is a true neoplasm which is defined radiologically as a radiolucent, expansile, well-defined lesion with variable calcification. It can be unilocular or multilocular with cortical thinning and possible perforation. Pain is rare. There are two subtypes, trabecular and psammomatoid, which have different histopathological appearances.

Surgical excision is recommended and this may need to radical as recurrence rates are high (30–50%) probably due to the propensity of this disease to perforate cortical bone. Malignant change has not been reported.

Bony malignancies can rarely present as nasal obstruction or deformity; good-quality imaging will usually alert the clinician to the need for further investigations.

BEST CLINICAL PRACTICE

- ✓ Use of an oral airway in neonates with nasal obstruction can facilitate transfer for definitive treatment.
- ✓ Minimal additional investigations for a child with choanal atresia to look for CHARGE syndrome are echocardiography, renal ultrasound and ophthalmology/audiology review.
- ✓ Early surgical excision of dermoid cysts is recommended before infection or further expansion occurs.
- ✓ Nasal masses may not be as innocuous as they seem; always consider intracranial extension and imaging with CT (for bony anatomy) and MRI (to identify a CNS connection).
- ✓ Compression of the internal jugular vein (Furstenberg's test) usually causes an encephalocoele but not a glioma to enlarge.
- ✓ The treatment of nasal haemangiomas has been revolutionized by propranolol.
- ✓ Idiopathic neonatal rhinitis is underdiagnosed and improves with intranasal steroids.
- ✓ The endoscopic approach is rapidly becoming the procedure of choice for removal of neonatal nasal masses.

FUTURE RESEARCH

- ➤ Multicentre studies including long-term follow-up of patients who undergo surgery for choanal atresia.
- ➤ Studies looking at the success rates of the endoscopic approach for nasal encephalocoeles and gliomas are needed.
- ➤ Long-term follow-up of neonates who have had closed reduction of their septal deviation is unknown.
- ➤ Better evidence for the management of neonatal rhinitis is needed.

KEY POINTS

- Neonates are obligate nasal breathers; nasal obstruction can cause significant airway compromise.
- Affected neonates may develop stertor, mouth-breathing, feeding problems, sleep disturbance and rhinorrhoea.
- Immediate relief can be brought about by insertion of an oral airway.
- Choanal atresia may occur in isolation but is often one of a number of associated anomalies.
- A congenital nasal mass can consist of ectopic intracranial tissue.

CHAPTER 24

PAEDIATRIC RHINOSINUSITIS AND ITS COMPLICATIONS

Daniel J. Tweedie

SEARCH STRATEGY

Data in this chapter may be updated by a Medline search using the keywords: paediatric (pediatric) rhinosinusitis, sinusitis, complications, respiratory tract infections, immune deficiency, reflux, primary ciliary dyskinesia, cystic fibrosis, orbital cellulitis, endoscopic sinus surgery, adenoidectomy, and with particular reference to international consensus papers: the European Position Papers on Rhinosinusitis and Nasal Polyps (EPOS, 2007 and 2012).[1, 2] The American Academy of Otolaryngology – Head and Neck Surgery (AAO-HNS) Consensus Statement on Pediatric Chronic Rhinosinusitis (2015)[3] and the International Consensus Statement on Allergy and Rhinology: Rhinosinusitis (ICAR:RS, 2016).[4] These documents have made use of multinational consensus expert opinion and consider the latest available evidence.

OVERVIEW

Rhinosinusitis in children is extremely common, typically following viral upper respiratory tract infection, but other factors may be involved.

Paediatric rhinosinusitis (RS) and its complications describe a spectrum of disease, varying in aetiology, pathophysiology and duration, which influences clinical presentation and management. Apart from exposure to the common viral precipitants, known predisposing factors include allergy,[5–8] impaired cilial function,[9] immune deficiency, gastro-oesophageal reflux,[10] environmental pollution, malnutrition, and medical conditions such as diabetes mellitus and other metabolic conditions.[2] There are also specific congenital and acquired disorders in which rhinosinusitis is often a major component, for example cystic fibrosis and primary ciliary dyskinesia, and these warrant special consideration.

Rhinosinusitis is common in children[11–14] but frequently overlooked. It is significantly detrimental to quality of life[15] and costly in health economic terms. For example, the estimated annual cost of treatment of sinusitis in children under 12 years of age in the USA in 2012 was $1.8 billion.[16] While paediatric and adult rhinosinusitis are often considered together, these conditions are multifactorial, with predisposing factors and aetiology changing with age, and the childhood and adult forms differ in a number of ways. These have been summarized in the EPOS 2007 document[1] and are shown in **Table 24.1**.

ANATOMY

The paranasal sinuses are air-containing spaces which are positioned around the nasal cavities, communicating with these via natural ostia. They are lined by type II pseudostratified columnar ciliated epithelium (respiratory mucosal epithelium), with anatomical factors and cilial function optimized to facilitate mucus drainage and preserve a sterile environment.[17]

Sinus development is progressive throughout childhood. At birth, the maxillary sinuses measure 7 mm in depth, 3 mm in width and 7 mm in height.[1] The sphenoidal (sphenoid) sinuses and two or three ethmoidal (ethmoid) cells are found on each side at this stage, and the ethmoid labyrinth is complete by 4 years of age. The frontal sinuses,

TABLE 24.1 The differences between paediatric and adult chronic rhinosinusitis (reproduced with permission[2])

	Young children	Adults
Commensal microflora		
Coagulase-negative staphylococci	30%	35%
Staphylococcus aureus	20%	8%
Haemophilus influenzae	40%	0%
Moraxella catarrhalis	24%	0%
Streptococcus pneumoniae	50%	26%
Corynebacterium species	52%	23%
Streptococcus viridans	30%	4%
Immunity	Immature: defective response to polysaccharide antigens (IgG2, IgA)	Mature, except in a subset
History	Self-limited in time (improves after the age of 6–8 years)	No history of spontaneous improvement after certain age
Histology	Mainly neutrophilic disease, less basement membrane thickening and mucus gland hyperplasia, more mast cells	Mainly eosinophils
Endoscopy	Polyps are rare, except in CF	Polyps frequently present
CT-scan	Younger child more diffuse sinusitis, involving all sinus	Sphenoid and posterior sinus less often involved

not present at birth, develop from cranial extension of the ethmoid cells. Once the roof of these frontal cells reaches the level of the upper orbit, at around the age of 5 years, they are termed 'frontal sinuses'. These are demonstrable radiographically in 20–30% of children by 6 years[18] and more than 85% by 12 years of age. The maxillary sinuses expand in parallel, reaching the same level as the nasal floor by 7–8 years of age, and are 4–5 mm below this by adulthood. The sphenoid sinuses extend posteriorly over the first 7 years, and are radiologically distinct in 85% of cases by this stage, completing growth by 15 years, although some posterior extension can be seen into adulthood. Sinus expansion subsequently mirrors the dimensional changes of the midface during adolescence and towards adulthood. The maxillary and ethmoid sinuses reach full size by the age of 15 or 16, and the frontal sinuses by 19 years of age.[19]

DEFINITIONS

A number of consensus statements have sought to define rhinosinusitis in terms of symptoms and duration, but in practice the clinical diagnosis of rhinosinusitis in children can be challenging, and the diagnosis can be overlooked.

Rhinitis and sinusitis typically coexist in the same affected individual, given the close proximity of the nose and paranasal sinuses and their common mucosal lining. Guidelines and consensus documents including EPOS, ICAR:RS and statements from AAO-HNS now typically use the term **rhinosinusitis**, as opposed to sinusitis, reflecting the clinical and pathophysiological picture.[1–4, 20–22]

In a similar fashion as for adults, EPOS 2012 defines paediatric rhinosinusitis clinically as follows:[2]

'Inflammation of the nose and paranasal sinuses characterized by two or more symptoms, one of which should be either nasal blockage/obstruction/congestion or nasal discharge (anterior/posterior nasal drip):

- +/– facial pain/pressure
- +/– cough (as opposed to reduction or loss of smell in the adult definition).

and either:

- endoscopic signs of:
  - nasal polyps, *and/or*
  - mucopurulent discharge primarily from the middle meatus, *and/or*
  - oedema/mucosal obstruction primarily in the middle meatus

and/or:

- CT changes:
  - mucosal changes within the osteomeatal complex and/or sinuses'.

These diagnostic criteria are very similar to those endorsed in the AAO-HNS Pediatric RS consensus statement.[3]

SEVERITY OF DISEASE

According to EPOS,[2] as for adults, the severity of paediatric rhinosinusitis can be classed as mild, moderate and

severe according to a patient-reported visual analogue scale (VAS). However, although also applied to children, this system has only been validated in adults to date. Using a 10 cm scale, between 0 (not troublesome) and 10 (worst thinkable), the patient (or parent) is asked to mark the severity, when asked 'How troublesome are your (or your child's) symptoms of rhinosinusitis?' A score of 0–3 is classed as mild, >3–7 moderate and >7–10 is severe. A score of greater than 5 indicates symptoms which affect patient quality of life.

DURATION OF SYMPTOMS: ACUTE VERSUS CHRONIC RHINOSINUSITIS

Paediatric chronic rhinosinusitis will be considered later in the chapter, although clinical assessment, investigation and treatment options are similar in certain aspects.

Acute rhinosinusitis (ARS) in children is defined by EPOS[2] as:

'Sudden onset of two or more of the symptoms:

- nasal blockage/ obstruction/ congestion
- *or* coloured nasal discharge
- *or* cough (daytime and night-time)

for <12 weeks (with symptom-free intervals if the problem is recurrent).'

The symptom profile defined by ICAR:RS[4] is similar, but with ARS defined by a duration of less than 4 weeks. Both consensus documents stress the inclusion of questions regarding allergic symptoms (sneezing, watery rhinorrhoea, itching of the nose and eyes), to help differentiate allergic from viral and bacterial RS.

The EPOS system[2] favoured the omission of previously used terms such as 'subacute' and 'acute or chronic' RS.

In practice, the diagnosis of ARS in children is challenging[2] due to the overlap with other conditions, including viral upper respiratory tract infections (URTIs) and the subjectivity of parental reporting of symptoms. Young children often do not tolerate nasal endoscopy, and radiographic investigations are often avoided on account of radiation exposure, particularly in children with a short-lived, uncomplicated history.

PAEDIATRIC ACUTE RHINOSINUSITIS

Epidemiology and pathophysiology

It is now known from CT[23] and MRI[24] studies that, in the majority of children with symptoms of mucous nasal discharge, the sinuses are also involved (in decreasing order of frequency: maxillary and ethmoid (60%), sphenoid (35%) and frontal (18%), with resolution of the changes seen on imaging in parallel with clinical improvement of symptoms.[24] Viral URTIs occur extremely frequently in young children (six episodes per year,[25] more in day care), and it is generally agreed (despite low rates of virus recovery from sinus aspirates[26]) that these are the precipitant for most cases of paediatric rhinosinusitis.[27,28] In prospective longitudinal studies in young children, some 8% of viral URTI cases in patients 6–35 months of age were complicated by acute RS, equivalent to 0.5 episodes per patient year.[25] Epidemiological studies also suggest that:

- RS is commonest in younger children, and the prevalence decreases sharply after 6–8 years of age, probably reflecting immune system immaturity at an early age.[29,30]
- Seasonal variations in the prevalence of RS reflect rates of viral URTI, with an increase in occurrence in autumn and winter.[29]
- Young children looked after in day care with other children have markedly higher rates of RS than those managed at home.

The annual medical visit rate in the USA for acute RS is stable, at 11–14 per 1000 children.[31] The durations of episodes of viral and bacterial RS are broadly similar between children and adults.

The commonest bacteria isolated from maxillary sinus aspirates in children with acute bacterial rhinosinusitis (ABRS) are *Streptococcus pneumoniae*, untyped *Haemophilus influenza* and *Moraxella catarrhalis*, and less often *Staphylococcus aureus, Streptococcus pyogenes* and *Streptococcus viridans* and anaerobes, including *Peptostreptococcus* and *Fusobacterium*, particularly in longer-lived cases.[26,32–41] Interestingly, adoption of the 7-valent pneumococcal vaccine (PCV) in the United States from 2000 onwards has resulted in a decline in positive samples of *Streptococcus pneumonia*, but relatively higher proportions of aspirates with untyped *Haemophilus influenzae*.[42,43] *Staphylococcus aureus* is relatively commonly isolated from cases of sphenoid sinusitis[39] and rates of methicillin-resistant *S. aureus* (MRSA) are increasing in cases of ABRS.[44,45] Importantly, such infections are often polymicrobial (about one-third of cases), and this should be borne in mind with respect to antimicrobial treatment. Similarly, less common pathogens must be considered in particular circumstances. Anaerobes comprise some 8% of bacterial isolates, often oral pathogens seen in cases of odontogenic origin, and particularly prevalent in cases persisting for more than 1 month.[36,46] *Pseudomonas aeruginosa* is associated with nosocomial infection, particularly in the immunocompromised[47] (including HIV cases), patients with nasal catheters and other devices, and those with cystic fibrosis.[48] In these sorts of cases, fungal rhinosinusitis may also develop (see below).

While remaining the gold standard for diagnosis of ABRS (≥10 000 colony-forming units per mL), antral puncture and aspiration is seldom undertaken. One should also bear in mind that improper decontamination of the paranasal mucosa before aspiration may lead to misinterpretation of results.[26,49–51] As an alternative, cultures

from the middle meatus can be obtained, for example with endoscopic guidance.[52] The maxillary sinus aspirates correlate well with specimens taken from the middle meatus of the nasal cavity (83%) but poorly with those from the nasopharynx (45%).[53]

Clinical presentation of paediatric ARS: symptoms and signs

In the paediatric group, ARS typically presents with a combination of prolonged URTI, chronic cough, nasal discharge, plus fever >39 °C and facial pain in many cases. Most cases are viral in aetiology, but bacterial infection should be considered in cases with persistent and severe symptoms and those with deterioration after initially mild symptoms.

In terms of relative preponderance between acute and chronic RS, nasal, local and systemic clinical features differ,[30, 54, 55] as summarized in the EPOS 2007 document[1] and shown in Table 24.2.

Apart from these symptom differences between acute and chronic forms, the distinction in definition is made according to symptom duration, as above, recognizing the common scenario of a child with symptoms of chronic RS who also has infection-related acute exacerbations.

Classification of paediatric ARS by aetiology

As with the definitions and criteria discussed above, there is some variation between consensus documents regarding the aetiological classifications and diagnostic features differentiating the subtypes of acute paediatric RS.

For children, as for adults, EPOS,[1, 2] ICAR:RS[4] and the American Academy of Otolaryngology – Head and Neck Surgery (AAO-HNS)[3] define **acute viral rhinosinusitis** (viral ARS, common cold), where nasal symptoms are present for less than 10 days. The most recent guidelines from the AAO-HNS included data on the duration of typical viral symptoms in support of the commonly accepted time frames used to differentiate acute viral RS from ABRS.

The EPOS 2012 statement[2] describes **acute post-viral rhinosinusitis** as an increase of symptoms after 5 days, or persistent symptoms after 10 days, but with symptom duration of less than 12 weeks. This is not recognized separately by the AAO-HNS guidelines.

Acute bacterial rhinosinusitis (ABRS) is diagnosed clinically, according to EPOS,[2] by the presence of at least three of:

- discoloured discharge (with unilateral predominance) and purulent secretion in the nasal cavity
- severe local pain (with unilateral predominance)
- 'double sickening' - deterioration after an initial milder phase of illness
- elevated erythrocyte sedimentation rate (ESR)/C-reactive protein (CRP)
- fever (>38 °C).

The latter criterion is not considered diagnostically specific or sensitive for ABRS according to the AAO-HNS criteria.[3, 4]

For the clinician, the most common presentation of ABRS in children is a persistent and non-improving nasal discharge or cough (or both), which lasts for more than 10 days.[14] In children, the cough often worsens at night (in 80% of cases), with nasal symptoms (anterior/posterior discharge) in 76%, and associated fever for more than 3 days in 63%.[56] Halitosis is commonly seen in addition, but associated facial pain and swelling, headache and sore throats are unusual in children.

In terms of the variable clinical presentation, a number of consensus panels have identified the following three characteristic presenting features of ABRS which are diagnostically discriminating versus simple viral URTI.[57–60] Given the possible diagnostic difficulties already outlined, Wald identified three main clinical features which are suggestive of acute bacterial rhinosinusitis, over and above acute viral RS[61] which are supported by other studies:[9, 62, 63]

1. Persistent symptoms for more than 10 days, but less than 30 (although the EPOS documents define the duration of acute RS as up to 3 months).
2. Onset with severe symptoms (ill appearance, high fever >39 °C, purulent nasal discharge for at least consecutive 3–4 days at the onset of illness and other features including headache and facial pain).
3. Worsening after initial improvement (double sickening) is also strongly suggestive of ABRS.[58]

In non-allergic children, neutrophil proportions of ≥5% in nasal brushings have a 91% sensitivity and positive predictive value of 84% for maxillary sinusitis.[64]

TABLE 24.2 Presenting symptoms of rhinosinusitis in children (data reproduced with permission[2])

Symptom	Preponderance	Acute/chronic
Rhinorrhoea	71–80%	All forms
Cough	50–80%	All forms
Fever	50–60%	Acute
Pain	29–33%	Acute
Nasal obstruction	70–100%	Chronic
Mouth breathing	70–100%	Chronic
Ear complaints (recurrent purulent otitis media or OME)	40–68%	Chronic

Differential diagnoses

In children with nasal discharge, one should always exclude the possibility of a nasal foreign body or choanal stenosis or atresia. Dental disease may also give rise to sinonasal and facial symptoms. These cases most typically

present with unilateral findings, and often a suggestive history. These can usually be excluded with careful examination, including nasal endoscopy.

Hypertrophy and inflammation of the adenoids (adenoiditis) may also present with nasal obstruction and mucus. This tends to be more long-standing, with a suggestive parental history. Again, nasal endoscopy is useful to determine this.

Similarly, parental history may suggest allergic rhinitis as the basis for nasal symptoms.[65]

Clinical assessment of a child with acute rhinosinusitis

Considering the clinical features outlined above, the history and clinical examination should be focused towards confirming the diagnosis of ARS, distinguishing likely bacterial versus viral aetiology and excluding local and systemic complications.

HISTORY

The history should include enquiry about current symptoms, past history and risk factors (**Box 24.1**).

CLINICAL EXAMINATION

The clinical examination may be challenging in young children, but should ideally include:

- general observations, including temperature and neurological status
- complete ENT and head and neck examination (including the pharynx, oral cavity and teeth, orbits, ocular motility, vision, facial palpation and percussion over the paranasal sinuses, pupillary responses, cranial nerves)
- anterior rhinoscopy (oedema, inflammation, mucus/pus, foreign body) – this can by lifting up the tip of the nose and/or use of an otoscope[66, 67]
- nasal endoscopy (rigid or flexible), including middle meatal swabs for culture and sensitivity.

BOX 24.1 Clinical assessment – history

Current symptoms	Past history and risk factors
Onset	Similar episodes of sinusitis and RTI
Duration	Previous use of antibiotics
Precipitants (viral URTI, nasal foreign body)	Comorbidities
Improvement and deterioration in clinical picture ('double sickening')	Prior hospitalization and sinonasal surgery
Nasal/paranasal symptoms (congestion, mucopurulent discharge)	Allergy history
Facial/orbital pain or swelling	Day-care arrangements
Headaches and neurological sequelae	Exposure to cigarette smoke
Cough	Immunization history
Fever (severity and duration)	
Hyposmia	
Oral/dental/pharyngeal symptoms	

The nasal and pharyngeal mucosa is typically erythematous, with yellow/green nasal discharge of varying consistency. Studies have suggested the relative prevalence of associated features: post-nasal drip of mucus into the pharynx in 60%,[55] middle meatal pus in 50% and oedema of the inferior turbinates in 29%.[54] Adenotonsillar enlargement and modest, tender cervical lymphadenopathy is also sometimes seen.[66, 68]

Acute fungal rhinosinusitis in children

This is rare, and diagnosis and workup are already considered in Vol 1, Chapter 94. Allergic fungal rhinosinusitis is addressed later in this chapter.

Investigations in children with rhinosinusitis

The relevance and relative indications for investigations will depend upon the clinical presentation of rhinosinusitis, including the duration and severity of symptoms, complications and underlying comorbidities. For example, an acute, infective episode will direct a different investigative approach than a chronic, inflammatory case, where atypical organisms and/ or underlying inflammatory conditions or immunocompromise might be suspected.

Although microbiological and radiological investigations are certainly indicated in complicated cases, in most instances a clinical assessment of the child with acute RS is sufficient. In chronic RS, unusual organisms may be involved, and surgery may be warranted, prompting investigations to inform further management (see below).

MICROBIOLOGY

Cultures from nasal mucus are not needed in most cases of uncomplicated ARS. But there are some situations where this is needed. As mentioned above, antral aspiration, with measures to reduce contamination, remains the gold standard although it is impractical in everyday practice. This is reserved for particularly severe or resistant cases, or where surgical intervention is undertaken. An alternative method is to take a swab from the maxillary sinus[52] under endoscopic guidance. Nasal contamination is suggested by low bacterial quantities in the sample from a patient with significant symptoms, highly suggestive of acute bacterial RS, so isolates are considered positive when they contain more than 10 000 CFU/mL.[61]

Indications for culture are:[69]

- severe symptoms and toxic patient
- illness not improving after 48–72 hours of medical treatment
- immunocompromised patient
- suppurative complications (orbital, intracranial) or systemic sepsis.

IMAGING

The diagnosis of rhinosinusitis in children is typically clinical and usually does not require imaging. In any event, radiological investigations will not distinguish between viral and bacterial RS.[70]

Transillumination and ultrasound have been considered, but are limited in young children by thickness of soft tissues and the hard palate.[71] Plain sinus radiographs, once in common use, are now not indicated in the investigation of RS, as they correlate very poorly with CT findings. More than 50% of children with viral URTI will have abnormal maxillary sinus radiographs.[72] The radiation exposure is not justified in these circumstances.[23]

Imaging is occasionally indicated, for the same reasons as for microbiological culture above. Computerized tomography (CT) is the modality of choice, with intravenous contrast if intracranial complications are to be excluded. This is performed very quickly, usually without the need for sedation, and it is therefore favoured over MRI for these reasons.[73] But it is important to note that even asymptomatic children have a high incidence of abnormalities on CT,[72, 74] which by definition require no treatment. Additionally, in young adults, it has been found that 87% of those recovering from a viral URTI have maxillary sinus changes on CT.[27] Therefore any CT abnormalities in patients with RS must be correlated against clinical findings.

While CT has many advantages, MRI offers greater soft-tissue resolution[56] and does not involve any radiation exposure. The American College of Radiology has commented that CT and MRI are complementary modalities in the investigation of suspected orbital and intracranial complications of ABRS.[75] However, the bony resolution of CT is essential if surgery is considered, particularly given that the size of the developing sinuses in children often differs significantly on the two sides. This can be combined with image guidance systems at the time of surgical intervention. In addition, the practicalities and speed of CT and its widespread availability mean that it remains the most frequently used radiological modality in cases of RS, often as a sole imaging investigation.

Treatment of acute rhinosinusitis in children

The evidence based management of children with ARS has been presented very clearly in the EPOS 2012 document,[2] and is outlined in **Table 24.3**.

TABLE 24.3 Treatment evidence and recommendations for children with acute rhinosinusitis (reproduced with permission[2])

Therapy	Level	Grade of recommendation	Relevance
Antibiotic	Ia	A	Yes, in ABRS
Topical steroid	Ia	A	Yes, mainly in postviral ARS studies only done in children 12 years and older
Addition of topical steroid to antibiotic	Ia	A	Yes, in ABRS
Mucolytics (erdosteine)	1b (–)*	A(–)**	No
Saline irrigation	IV	D	Yes
Oral antihistamine	IV	D	No
Decongestants	IV	D	No

*1b (–): 1b study with negative outcome; **A(–): grade A recommendation **not** to use.

ANTIBIOTICS

Antibiotics are the mainstay of management of children with ARS. Meta-analysis of randomized controlled trials (RCTs), which included 17 studies (three of these in children), and 2915 adults and 376 children) showed an increase in resolution of symptoms. This effect was significant but modest,[76] and suggests that antibiotics may simply hasten slightly the resolution of uncomplicated cases of ARS, but that most cases will improve, irrespective of treatment.

The choice of antibiotics should ensure activity against the likely organisms, and include amoxicillin, amoxicillin-clavalunate and cephalosporins (the latter two covering beta-lactamase-producing organisms). Other options for patients with allergies to these agents include macrolides (azithromycin, clarithromycin) or trimethoprim/sulfamethoxazole. There is no formal recommendation for dose and duration of antibiotic use, which may be adjusted according to severity of symptoms and other factors.

INTRANASAL STEROIDS

There is evidence to support the use of intranasal steroids in conjunction with antibiotics in the management of children with ARS. In a specific paediatric trial, where 89 children received amoxicillin-clavalunate and either intranasal budesonide or placebo, significant improvements were seen by the end of the second week in those receiving intranasal steroids compared to placebo.[77] A number of other trials have considered adults and older children (12 years and above), demonstrating benefits in those receiving intranasal steroids during ARS, typically with antibiotics.[2, 77] However, while there is also evidence to

support the safety and efficacy of intranasal steroids for allergic rhinitis in younger children, data are so far lacking for ARS in this group, and the benefits are less certain. Therefore clinical judgement on an individual basis will determine whether intranasal steroids are offered in this context, most likely as an adjunct to antibiotics.

OTHER MEASURES

While saline douching may offer some benefit in children with ARS, there is no strong evidence to support the use of mucolytics and oral antihistamines in this context.[57]

Complications of paediatric acute rhinosinusitis

With the advent of antibiotics and improved standards and availability of medical care, the incidence and associated mortality from complications of paediatric ARS has declined. But these complications still occur and require prompt diagnosis and specialized management.

The overall rate of complications is 3–10 cases per million per year, equivalent to 1 per 12 000 ARS episodes.[2] Complications are more often seen in winter months,[78] and significantly more often in males than females. Importantly, studies from the Netherlands and the UK have shown that prescribing antibiotics in ARS does not prevent the occurrence of complications.[79, 80]

Complications occur as follows, although in some cases a combination may be seen:[81] orbital (60–75%), intracranial (15–20%), osseous (5–10%).

Rhinosinusitis is the presumed underlying cause in many cases of peri-orbital sepsis (10% of cases of preseptal cellulitis, 90% of cases of orbital cellulitis/subperiosteal abscess/orbital abscess)[82] and about 10% of intracranial suppuration.[83, 84]

Orbital complications are more often seen in small children, although intracranial complications can occur at all ages, particularly in the second and third decades of life.[79, 85]

ORBITAL COMPLICATIONS

Orbital complications can occur as a result of direct spread of infection across the lamina papyracea, or via a haematogenous route through small veins.[86] This is most likely from the ethmoid sinuses, and less often the maxillary, frontal and sphenoid sinuses in decreasing frequency.[79, 87] Such complications may occur with minimal pain or systemic upset.[88]

The Chandler classification is widely used to describe orbital complications of ARS[81] with respect to the orbital septum. This identifies five stages of orbital sepsis:

1. Inflammatory oedema (preseptal cellulitis)
2. Orbital cellulitis
3. Subperiosteal abscess
4. Orbital abscess
5. Cavernous sinus thrombosis.

It should be noted, however, that these are not necessarily seen clinically in a sequential manner. For example, intracranial complications including cavernous sinus thrombosis (see below) may occur without prior abscess formation. Additionally, the inclusion of preseptal cellulitis has also been questioned, which by definition is not an orbital infection, and is far less commonly seen as a result of ARS than true orbital complications. Other classification systems have therefore also been considered.[89, 90]

Preseptal cellulitis

Preseptal cellulitis describes inflammation of the eyelid and conjunctiva, anterior to the orbital septum). It may occur as a complication of upper respiratory tract infection, dacryocystitis or skin infection and less often sinusitis.[91–94] Presenting features include eyelid oedema and erythema, orbital pain, with or without fever and systemic upset. There is typically no proptosis or restriction of eye movements, but this can be challenging to assess in small children.

Preseptal cellulitis usually responds to an oral antibiotic but may spread beyond the orbital septum, with intraorbital complications. As such, it can usually be assessed clinically, but imaging is sometimes considered.

True orbital complications, while presented individually, can be considered together in terms of a more severe clinical presentation, and require far more aggressive investigation and management strategies.

Orbital cellulitis

Orbital cellulitis and subperiosteal abscess are seen more commonly than preseptal cellulitis as a result of ARS.[91, 93] Inflammation behind the orbital septum, within the tight confines of the orbit itself, will reduce the range of eye movements and produce pain on movement, diplopia, chemosis (conjunctival oedema) and proptosis. This requires a proactive management regime, including treatment with intravenous antibiotics and cross-sectional imaging to exclude orbital or intracranial abscess and other complications.

Subperiosteal and orbital abscess

A subperiosteal abscess forms between the periorbita (soft tissue orbital contents) and the sinuses, and is 'extraconal', lying outside the cone of ocular muscles. The clinical features of a subperiosteal abscess are similar to those of orbital cellulitis: oedema, erythema, chemosis and proptosis with painful, limited eye movements. Systemic upset and derangement of inflammatory markers may be more pronounced[95] but they cannot be relied upon to discriminate an abscess from cellulitis.

Orbital abscess is less commonly seen, with a frequency of between 8.3%[96] and 13% in studies of orbital complications in children.[97] This is 'intraconal', within the cone of the ocular muscles, and may result from diagnostic delay or immunosuppression.[98]

MANAGEMENT OF ORBITAL COMPLICATIONS

Orbital complications and their management are considered together, although in some cases these can coexist with intracranial and osseous complications, in many cases with similar investigation and treatment strategies. The child's vision is at risk, and there is also the possibility of life-threatening intracranial complications. The importance of a high index of suspicion, comprehensive history and clinical assessment cannot be overstated, as well as a considered, proactive approach to investigation, medical and surgical management. This mandates a multispeciality approach, with input from otolaryngology, paediatrics, ophthalmology, neurosurgery and microbiology personnel.

Clinical assessment

Considering the clinical features above, history and examination should include assessment of the eyes with respect to swelling, proptosis, movements, colour vision and acuity, plus assessment of the child's general condition, vital signs, level of consciousness and neurological status. This is undertaken with help from paediatric and ophthalmology colleagues. Twice-daily ophthalmology review of colour vision and acuity is recommended.[99] If there is failure to respond to medical management or otherwise any clinical suspicion, cross-sectional imaging is indicated.[99]

The first-line investigation is CT with contrast, including orbital detail, the paranasal sinuses and brain, with a view to assessing orbital and intracranial complications adequately. This is usually quick to perform and normally possible in an awake child. CT may allow distinction between cellulitis and orbital/subperiosteal abscess. In the case of subperiosteal abscess, findings include oedema of the medial rectus muscle, lateralization of the periorbita, and displacement of the globe downward and laterally. Orbital abscess is associated with obliteration of the detail of the extraocular muscle and the optic nerve by a confluent mass, sometimes with gas bubbles from anaerobic bacteria.

The predictive accuracy of a clinical diagnosis has been found to be 82% and the accuracy of CT 91%. MRI may be useful in cases of diagnostic uncertainty or when intracranial complications are suspected,[100, 101] but this usually requires sedation or general anaesthesia in young children, so this should not delay management.

Treatment

Initial medical treatment consists of high-dose intravenous antibiotics (according to local protocols), covering aerobic and anaerobic organisms, plus analgesia/antipyretics, intravenous fluids and adjuncts including intranasal steroids and saline douching. Antibiotics can be converted to an oral preparation when the patient has been afebrile for 48 hours.[102]

Where there is evidence of an abscess on CT and/or absence of clinical improvement after 24–48 hours of intravenous antibiotics, orbital exploration and drainage is indicated.[96] Current consensus from the EPOS 2012 document[2] suggests that preseptal and orbital cellulitis should be treated with antibiotics, while subperiosteal and intraorbital abscesses require surgical exploration.

In adults, drainage may be attempted endoscopically in expert hands, with adjuvant endoscopic sinus surgery (including ethmoidectomy)[95] and the consensus is to attempt to drain the abscess endoscopically by opening the lamina papyracea and draining the abscess after completing an endoscopic ethmoidectomy. However, in children with small noses and paranasal sinuses and marked nasal congestion, access and the quality of the endoscopic surgical field may be extremely unfavourable, such that external approaches (via a modified Lynch Howarth incision in the case of medial subperiosteal abscess or eyelid approaches for superior/lateral orbital abscess) are often used.

However, good outcomes can be seen with non-surgical management, with intravenous antibiotics in small children with subperiosteal abscess,[98, 100, 102] provided the following apply:

- There is clinical improvement within 24–48 hours.
- There is no decrease in colour vision or visual acuity.
- The abscess is subperiosteal and small (<0.5–1 mL volume) and medially located.
- There is no significant systemic involvement.
- The patient age is less than 2–4 years.

Sequelae of orbital complications

Where management has been prompt and appropriately directed, patients will usually recover very well with minimal long-term problems. However, in some cases vision may be permanently compromised or lost as a result of retinal artery occlusion and/or prolonged venous congestion, optic neuritis and corneal ulceration. There are also risks of diplopia and other long-term orbital complications resulting from the original infection and/or surgical drainage procedures. Sepsis may also spread intracranially.[103] Careful follow-up is therefore required to identify these issues.

INTRACRANIAL COMPLICATIONS

Intracranial complications include abscess formation (extradural, subdural or intracerebral), meningitis, cerebritis and dural venous thrombosis (including superior sagittal and cavernous sinus thrombosis).[83, 104, 105] These are most often associated with frontoethmoidal or sphenoidal ARS,[105] via direct extension or haematogenously via diploic veins.[106] Flora is often mixed aerobic/anaerobic, so the antibiotic cover should reflect this, if possible corroborated with culture of pus samples. Common pathogens in this context are *Streptococcus* and *Staphylococcus* species and anaerobes.[83]

A high index of suspicion is required, as the clinical presentation of intracranial sepsis is often non-specific, including high fever with severe, intractable headache, but

sometimes such symptoms are absent (masked), especially in immunocompromised patients and those who have had prolonged antibiotic therapy already.[101] However, in most cases, specific signs and symptoms are present, including nausea and vomiting, neck stiffness and altered mental state.[98, 103, 104, 106] Intracranial abscesses are often heralded by signs of increased intracranial pressure, meningeal irritation, and focal neurologic deficits, including cranial nerve palsies (III, VI and VII), or more generalized neurological deficit (altered consciousness, gait disturbance, confusion).[98, 107]

As with orbital complications, CT with contrast allows an accurate delineation of bone involvement. MRI is an excellent adjunct, especially where neurosurgical intervention is being considered. It is more sensitive than CT in discriminating intracranial complications,[108] with particular value in venous sinus thrombosis, or where there is soft-tissue involvement. The same considerations apply in terms of availability of MRI and likely requirement of general anaesthesia in young children.

Options for culture include swabs from the nose (with endoscopic guidance if practical), sampling of pus during formal sinus surgery or during neurosurgical drainage, plus blood cultures and lumbar puncture (after first excluding raised intracranial pressure).

As for intraorbital abscesses, drainage of intracranial abscesses is usually undertaken (neurosurgical burr hole drainage, craniotomy or image-guided aspiration), as needed. Combined drainage of the paranasal sinuses can be performed endoscopically or via an open approach.[108] In some cases, where abscesses are small and/or inaccessible, non-surgical management may be reasonable, only after expert neurosurgical consideration. High-dose long-term antibiotic therapy is often needed.[109, 110]

Cavernous sinus thrombosis

This potentially devastating complication is seen where veins around the paranasal sinuses are congested during ARS, and become phlebitic, with propagation centrally. This can lead to cavernous sinus thrombophlebitis causing sepsis and multiple cranial nerve involvement.[111] This accounts for around 9% of intracranial complications,[106] particularly after ethmoidal or sphenoidal sinusitis.[112] In adults, the mortality rate is 30%. No such data are available for the paediatric population, where the mortality rate for intracranial complications has been quoted at 10–20%.[113]

Clinical features include:[114]

- bilateral ptosis
- proptosis and chemosis
- ophthalmic nerve neuralgia
- retro-ocular headache, which can be severe
- complete ophthalmoplegia,
- papilloedema
- signs of meningeal irritation, associated with spiking fevers
- confusion and reduced level of consciousness.

Similar investigations will be required as for other forms of intracranial complications. MRI (in particular MR venography) is especially sensitive, with absence of flow in the thrombosed sinus. As an alternative, CT with contrast may show equivalent filling defects.

Treatment is undertaken in a specialist neurosurgical centre. Anticoagulants may be considered, as long as imaging has excluded intracerebral haemorrhage, in conjunction with intravenous antibiotics and/or steroids. Drainage procedures will include attention to the involved paranasal sinuses.

OSSEOUS COMPLICATIONS

ARS may lead to infection spreading to the surrounding bone, producing osteomyelitis and in some cases onward spread to the brain and central nervous system. The frontal sinuses are most often implicated, but ARS in any of the sinus groups may produce similar sequelae, particularly in infancy, where the maxillae can be affected.[114, 115]

Osteomyelitis produces avascular necrosis of bone and localized venous congestion. In the case of the frontal sinus, erosion of the anterior table in this way causes oedema of the overlying skin (Pott's puffy tumour). Spread via the posterior table can give rise to meningitis and other intracranial complications, with similar signs. The changes are well delineated by CT, with MRI as an adjunct if intracranial complications are suspected.

The incidence of these complications has been well documented in adults, but is less certain in children, although overall these are relatively rare events. Management, as with other complications, demands a circumspect, proactive approach, often requiring multimodality treatment under the care of a variety of specialities.

PAEDIATRIC CHRONIC RHINOSINUSITIS

Chronic rhinosinusitis (CRS) (with or without nasal polyps) in children is defined by EPOS[2] as:

'Inflammation of the nose and paranasal sinuses characterised by two or more symptoms, one of which should be either nasal blockage/obstruction/congestion or nasal discharge (anterior/posterior nasal drip):

- +/– facial pain/pressure
- +/– cough
- persisting for >12 weeks.'

This duration is endorsed by the ICAR:RS[4] and AAO-HNS[3] consensus statements.

Clinical overview

Paediatric CRS has not been as extensively studied as in adults. The relative contribution of anatomical and other factors will differ between children and adults. Only a minority of cases present for treatment, and this is

typically medical, with surgery reserved for more resistant and severe cases.[2]

While the above definition is clear, confirming a diagnosis of CRS in children is often challenging or even impossible.[2] The precise history may be difficult to establish, particularly separating persistent symptoms lasting more than 12 weeks from frequently recurrent symptoms, interspersed with short periods of remission. Examination is not always straightforward, nasal endoscopy may not be tolerated and imaging is withheld in most cases. Even when CT scanning is undertaken, it should be noted that 18–45% of normal controls may have sinus-related changes.[116, 117] In one study, children without CRS were found to have a mean Lund-MacKay score of 2.8.[118] With this in mind, it has been proposed that a Lund-MacKay score greater than 5 in children indicates CRS,[119] but in reality most children with CRS will be managed on a clinical basis and will not undergo imaging.

There is also significant overlap with other very common childhood upper respiratory conditions, including recurrent viral URTI, allergic rhinitis and adenoiditis and/or adenoidal hypertrophy. In fact, the EPOS 2012 consensus group deemed it impossible to distinguish CRS from adenoid-related pathology in young children.[2]

Given these clinical and diagnostic uncertainties, it is important to establish which clinical features have the highest positive predictive value for CRS. Studies have suggested that the four most common features are:[120, 121]

- cough, particularly chronic cough
- rhinorrhoea
- nasal congestion
- post-nasal drip.

One study examined the correlation between chronic cough (>4 weeks) and CT sinus changes. In these patients, abnormalities on sinus CT were found in 66% of cases, with mild changes in 14%, moderate changes in 19% and severe changes in 33% of all cases.[122]

Pathophysiology of paediatric CRS

Some of the contributing factors in children with ARS will also apply in CRS, but it is worth considering separately the particular factors involved in CRS. This also applies to the differences in aetiology, pathology and management of CRS between children and adults.

Normal function of the nose and paranasal sinuses depends upon the health and integrity of the ciliated, columnar mucosal epithelium, and the overall anatomical pathways for mucus clearance, aeration and sinus drainage. The osteomeatal complex (OMC) is central to these considerations, which functionally represents the final common drainage pathway for the majority of the paranasal sinuses (frontal anterior/middle ethmoid cells and maxillary sinuses). The OMC comprises five structures:

- **maxillary ostium:** the main drainage channel of the maxillary sinus into the middle meatus
- **infundibulum:** a common channel draining the ostia of the maxillary and ethmoid sinuses to the hiatus semilunaris
- **bulla ethmoidalis:** a single air cell which projects inferomedially over the hiatus semilunaris
- **uncinate process:** a crescent-shaped process arising from the posteromedial aspect of the nasolacrimal duct, forming the anterior border of the hiatus semilunaris
- **hiatus semilunaris:** the final drainage passage, between the bulla ethmoidalis superiorly and free edge of the uncinate process.

The sphenoid and posterior ethmoid cells drain separately into the sphenoethmoidal recess.

The region of the OMC is subject to significant anatomical variation, often with little effect on sinonasal function. But mechanical obstruction of this area, as a result of congenital malformation, trauma, surgery and, more commonly, mucosal inflammation, may greatly impair its functional efficacy. This is considered to be the key event in most cases of chronic rhinosinusitis, although a diverse group of precipitating factors are involved. Obstruction of sinus drainage leads to retained secretions, reduced sinus aeration, mucosal hypoxia and dysfunction. Mucosal oedema and cilial impairment, with stimulation of further mucus production, lead to mucus stasis, further secretion retention and secondary infection.[56]

Contributing factors in paediatric CRS

With these considerations in mind, contributing factors for CRS in children can be subdivided into local/anatomical, inflammatory and infective, and systemic (**Box 24.2**).[56]

BOX 24.2 Contributing factors in paediatric CRS

Local factors	Inflammatory and infective factors	Systemic conditions
Sinus obstruction (anatomical, e.g. concha bullosa)	Viral URTI	Immune deficiency
Septal deviation	Bacterial infection	Cystic fibrosis
Nasal polyps	Allergy	Primary ciliary dyskinesia
Adenoidal inflammation	Gastro-oesophageal reflux disease (GORD)	
Trauma/iatrogenic	Tobacco smoke	
Foreign body		

The variation in contributing factors, and indeed the heterogeneity of individual anatomical variations and comorbidities, necessitates a circumspect approach in the investigation and management of such cases. Some particular issues warrant special consideration and are discussed below.

MICROBIAL FLORA

Microbial involvement in the pathogenesis of CRS has been increasingly considered, in addition to the cases of acute and chronic infection with the typical bacterial pathogens associated with ARS (above). It has traditionally been thought that the paranasal sinuses are sterile, but some studies have now suggested that this is not the case. In fact, reduced diversity of sinus microbial flora has been demonstrated in some cases with CRS, compared to healthy controls.[123] *Lactobacillus sakei* was shown in murine models of CRS to have a protective effect. In cases of CRS, it could therefore be possible that use of antibiotics may reduce the naturally protective effects of these organisms.

BACTERIAL INFECTION: EXOTOXINS AND BIOFILMS

On the other hand, infection by pathogenic organisms (as opposed to colonization by non-pathogenic flora) is a precipitant in some cases. The organisms involved are those which are typically implicated in acute bacterial RS (above). The mechanisms whereby these infections lead on to CRS are under review. Bacterial exotoxins may have an important role, with provocation of an excessive immune response by these mediators. For example, in patients with inflammatory nasal polyps, staphylococcal exotoxins have been found to affect T-cell function.[124] Biofilms (aggregates of bacteria within an external matrix of proteins, nucleic acids and polysaccharides) are also thought to be important, greatly decreasing the efficacy of antimicrobials. In fact, biofilms have been found in up to 80% of sinus biopsies from patients undergoing functional endoscopic sinus surgery (FESS),[125] and adenoid tissue, abundant in young children, may also harbour large volumes of biofilms, contributing to these processes.[126]

ADENOIDS

The role of the adenoids in the pathogenesis of paediatric RS, especially in chronic cases, is increasingly appreciated. It is also known that adenoidectomy reduces or eliminates symptoms in a high proportion of children with CRS. This is covered extensively in the EPOS 2012 document.[2] Several findings from a number of studies have highlighted this presumed aetiopathologic relationship.

- **Bacterial 'reservoir'.** In children with CRS, the bacteria cultured from middle meatal swabs and adenoidal core cultures are very similar, including *Streptococcus pneumoniae*, group A streptococci, *Haemophilus influenzae*, *Staphylococcus aureus* and coagulase-negative staphylococci.[127] The positive predictive value of adenoid core culture in predicting middle meatal culture results in one study was 91.5%, with a negative predictive value of 84.3%.[127]

  Interestingly, adenoid size alone has not been shown to correlate with the severity of disease on CT,[128] suggesting that the role of the adenoids as a reservoir for bacteria and associated inflammation ('adenoiditis') is more relevant than the size of the tissues (pure adenoidal hypertrophy).
- **Biofilms** are thought to have an important role within inflamed adenoid tissues in cases of adenoiditis and are also implicated in CRS in children, in the same patients. One study compared the biofilm volume on the surface of the adenoids excised in cases of adenoiditis/CRS versus those removed purely for obstructive symptoms. Although carried out in small numbers of cases, there was a major difference in the surface area of the adenoid tissue covered in biofilms between children with CRS symptoms, (88–99% of the surface area) and those with simple obstruction (0–6.5% of the surface area).[129]
- **Immunological effects** of the adenoid tissue have also been considered. In cases of CRS, adenoid tissue has lower IgA expression than in comparable tissue of children with simple adenoidal hypertrophy but no CRS symptoms.[130] Conversely, inflammatory markers (such as tissue remodelling cytokines, transforming growth factor β (TGF-β1), matrix metalloproteases MMP-2 and MMP-9) were found at higher levels in the adenoids of CRS patients than in controls.[131]

These studies, while small, correlate well with the near-identical clinical pictures of CRS and adenoiditis in children, and the relative benefit of adenoidectomy, independent of adenoid size, in the management of these patients. This is further addressed in 'Surgical management' below.

GASTRO-OESOPHAGEAL REFLUX DISEASE

Gastro-oesophageal reflux disease (GORD) is now recognized as a feature in a proportion of children with CRS. A large retrospective study comparing children with a diagnosis of GORD with non-reflux controls showed significantly higher rates of diagnosis of concomitant RS than in the non-reflux group (4.19% vs 1.35% respectively).[132] Effective antireflux therapy has been shown to reduce the need for sinus surgery in many of these cases.[133] But the presence of these conditions together, while suggestive, does not confirm a causal relationship. Further controlled trials will be required before antireflux medical treatment of children with CRS can be recommended routinely.

ALLERGY AND ALLERGIC RHINITIS

Children with CRS will often have an atopic history, including allergic rhinitis. But both conditions are common within the paediatric population and, again, their coexistence within the same individual does not demonstrate causality *per se*.

A number of studies have examined this relationship, albeit comprising relatively small numbers of children. Their findings are mixed, suggesting that the link between the two domains is not clear-cut. One examined the correlation between radioallergosorbent test (RAST) test and CT findings in patients (children and adults) with CRS symptoms which were resistant to treatment. Of 42 patients, 40% were atopic and 60% had negative RAST tests; the RAST-positive group also had more pronounced CT findings than the RAST-negative group.[134] But other studies have not shown significant correlations between atopic and non-atopic groups, either in terms of CT changes,[135, 136] or in the prevalence of atopy between children with and without a history of CRS.[137] The lack of consistent data has led the EPOS consensus group to suggest that there is probably no link between allergic rhinitis and CRS in children.[2]

ALLERGIC FUNGAL RHINOSINUSITIS

Allergic fungal rhinosinusitis (AFRS) results from hypersensitivity to fungi. It has a relatively high prevalence in adults with CRS who undergo surgery, and is estimated to occur in 5% to 10% of adults with chronic sinusitis who require surgery.[138] Children with allergic fungal rhinosinusitis may present with proptosis and polyposis.[139] Treatment includes sinus surgery to remove inflammatory tissue, polyps and fungus. Evidence is lacking for other treatments in children, although topical and systemic steroids and immunotherapy may be beneficial. The clinical diagnosis is easily overlooked, so a high index of suspicion is needed. Typical CT findings are unilateral sinus opacification with non-erosive expansion of the sinuses on CT.

ASTHMA

Some small studies examining the clinical course of children with asthma and CRS have shown marked improvements in asthma-related measures after medical and/or surgical treatment of CRS[120] (need for asthma medications, spirometry, wheezing and inflammatory markers in nasal lavage).[140] The improvements were seen to reverse once the CRS relapsed. These findings suggest that successful treatment of CRS in patients with asthma will help better control their chest symptoms, as is the case for allergic rhinitis. But while the links between asthma and allergic rhinitis are well documented, the relationship between asthma and CRS in children has not been demonstrated definitively by controlled trials.

IMMUNODEFICIENCY

A number of studies have evaluated the relationship between CRS in children and underlying immune deficiencies. These comprise series where cases of persistent CRS, which have been resistant to medical treatment, were investigated for a number of different immune parameters. Relatively small numbers of children were investigated in each series, with very variable results, including low IgA, Ig1 and/or Ig3 levels, poor pneumococcal antigen 7 responses in some cases (but normal vaccine responses in others).[141–143] Additionally, one study examined the clinical response of six children with refractory CRS who were treated with intravenous immunoglobulin for 1 year.[144] This showed a significant reduction in sinusitis episodes, total number of days of antibiotic usage and improved CT findings. These results suggest that various forms of immunodeficiency may have a role in a proportion of children with CRS, particularly in resistant cases. The EPOS 2012 consensus group therefore suggest evaluation of immune function in such cases, with quantification of Ig levels, and responses to various immunizations, including pneumococcal conjugate vaccine, tetanus and diphtheria.[2]

CYSTIC FIBROSIS

Cystic fibrosis (CF) is an autosomal recessive condition affecting 1 in 2500 live births in the UK, and is associated with high incidence of CRS and nasal polyposis in children. The mutated *CFTR* gene (cystic fibrosis transmembrane conductance regulator gene, long arm of chromosome 7–7q31.2) leads to abnormal cyclic AMP-mediated transmembrane chloride transport in epithelia and exocrine glands. This gives rise to multiorgan pathologies, including chronic pulmonary infections and bronchiectasis, pancreatic dysfunction and infertility. CRS is extremely common in these patients, and nasal polyposis is a feature in 7–50%.[145, 146]

Genetic testing and screening for suspected CF

More than 1000 mutations of the *CFTR* are known. The most commonly encountered mutation leads to a single amino acid deletion at position 508 in the *CFTR* protein (ΔF508). However, such is the number of possible mutations, and possible allelic combinations between individuals, that CF is not always straightforward to diagnose. It may be missed with screening, and can present variably (a disease spectrum), sometimes even into late childhood or adulthood.

Neonatal screening for the condition (as part of the Guthrie heel prick blood tests) has been offered universally in the UK since October 2007, having commenced earlier in some areas. This is also undertaken in a number of other countries. Blood levels of immunoreactive trypsinogen (IRT) are known to be high in cases of CF,[147] and this forms the basis of the CF component of the Guthrie test, undertaken universally within 5 days of life.

Babies with high IRT levels at or above the 99.5th centile are forwarded for genetic testing across four common loci (a four-panel DNA test, including ΔF508), with subsequent protocols designed to maximize accurate CF diagnosis as early as possible, while limiting parental anxiety associated with delays and false positives.

Babies with mutations in both *CFTR* genes have a presumptive diagnosis of CF and are reported as 'CF suspected', before referral to a paediatric service for evaluation (clinical assessment, sweat test and confirmatory mutation analysis).

Babies with one mutation detected will most often have a normal second allele, and are therefore

asymptomatic carriers. But a minority have an abnormal second allele which is not detected by the four-panel test. To identify such cases, a second IRT test is undertaken between day 21 and day 28, using a repeat dried blood spot specimen. Those with a high IRT on this second sample are reported 'CF suspected' and are referred as above, while those with IRT levels below a defined cut-off are considered probable carriers with a low risk of CF.

Those babies who have no detected mutation and a first IRT above the 99.5th centile but below the 99.9th centile are reported as 'CF not suspected'. Babies with an initial IRT at or above the 99.9th centile require a second IRT, as above, at 21–28 days; a second IRT below a given cut-off is reported as 'CF not suspected', but those with a high second IRT above the cut-off are considered 'CF suspected' and are referred on, with a presumptive diagnosis.

Sweat test

Owing to the great genetic heterogeneity of the condition, however, any genetic screening is accompanied by a sweat test, assaying the chloride levels in sweat induced by pilocarpine iontophoresis.[148] At the test site (usually the forearm), an electrode is positioned over gauze containing pilocarpine (a parasympathomimetic alkaloid) and an electrolyte solution. A second electrode is placed on untreated skin nearby, and a small electric current is applied, which draws sweat out of the skin. This is collected using preweighed filter paper over 30 minutes under controlled conditions to prevent contamination and evaporation.

Weighing and subsequent analysis of the sweat sample will determine the chloride level, and this is compared against age-appropriate levels (for children under or over 6 months of age). The sodium level should be commensurate with the chloride level. If not, then technical errors may be responsible; the reliability of the sweat test may be compromised by an insufficient sample, evaporation, contamination and other metabolic conditions, for example. A reliable positive test with high chloride levels on two separate days is diagnostic of CF.

Endoscopic sinus surgery in patients with cystic fibrosis

Surgical management of this group has been considered in the EPOS 2012 paper,[2] but studies are relatively small. The limited evidence from these studies suggests a significantly increased incidence of nasal polyps in children with CF, when compared with non-CF patients with CRS, and a high correlation between positive culture of *Pseudomonas* from sinonasal samples and underlying CF.[149] A further study demonstrated that, although certain measures, such as hospital admissions, were unaffected by ESS in this paediatric CF group, quality of life, nasal obstruction, discharge and other symptoms were significantly improved by ESS/polypectomy.[150] It would therefore appear reasonable to consider surgical management of children with CF who have sinonasal manifestations, bearing in mind the existing disease burden and the likelihood of symptom recurrence requiring multiple procedures throughout life. As such, the extent of surgery should be carefully considered on an individual basis, with the aim of maximizing benefits but limiting the risks of morbidity and complications.

PRIMARY CILIARY DYSKINESIA

Primary ciliary dyskinesia (PCD) is an autosomal recessive condition, involving dysfunction of cilia, present in 1 of 15 000 of the population.[151] The normal movement of mucus by mucociliary transport toward the natural ostia of the sinuses and nasopharynx is disrupted. Half of children with PCD also have situs inversus, bronchiectasis and CRS, collectively termed Kartagener syndrome. The diagnosis of PCD, like CF, should be suspected in children with atypical asthma, bronchiectasis, chronic wet cough or rhinosinusitis. Additionally, in PCD, children are prone to chronic and resistant otitis media, with persistent middle ear effusion. This tends to respond poorly to ventilation tubes, with persistent mucoid discharge.[9] Screening tests for PCD include nasal nitric oxide (NO) (with lower NO levels than controls) and the saccharin test, demonstrating slower mucociliary transit time from the anterior nares to the nasopharynx. Specific diagnosis involves examination of cilia (from mucosal brushings) by light and electron microscopy. In cases of PCD, this most often demonstrates lack of outer dynein arms, or a combined lack of both inner and outer dynein arms.[152] In contrast to CF cases, nasal polyposis is not typically encountered, despite significant sinonasal symptoms in many cases.[153]

Management of chronic rhinosinusitis in children

ASSESSMENT AND DIAGNOSTIC WORKUP

The clinical assessment of children with CRS is similar to that already described in cases of ARS. History, examination and further investigations should be targeted according to individual presentation, bearing in mind the possibility of underlying aetiologies, including adenoidal hypertrophy, and rarer conditions including CF, PCD, allergic fungal rhinosinusitis and immunodeficiency, for example. This heterogeneity of conditions demands a high index of suspicion when managing children with CRS, altering the threshold for referral for other specialist consultations and diagnostic tests, including cross-sectional imaging (CT and MRI) and culture of nasal samples. The sensitivity and specificity of sampling from the middle meatus (directly or under endoscopic visualization) for microbial culture has already been addressed.[52, 53]

Similarly, the rationale for CT and MRI, and their advantages and limitations have also been discussed.[119, 120] Plain radiographs do not correlate well with CT findings in CRS.[154] CT offers an excellent road map for surgical treatment, identifying anatomical variants and areas of bony erosion or distortion from disease.[155] Particular diagnoses in the context of CRS may be revealed by CT, for instance in the case of allergic fungal rhinosinusitis and CF. Characteristic features of AFS are expansile disease with attenuation of the skull base and orbital wall,

often with a 'starry sky' speckled pattern of high attenuation on soft tissue and bone windows, as a result of thick allergic mucin and calcification. This is corroborated by MRI, with low signal on T1 weighting in areas of mucin, with signal void on T2 weighting, plus a high signal rim of surrounding mucosal inflammation.[156]

In patients with CF, CT demonstrates panopacification of the sinuses and medial displacement of the lateral nasal wall, which may obstruct the nasal passages.[157]

MEDICAL THERAPY

In contrast to CRS in adults, young children with CRS typically can be managed conservatively, as symptoms tend to resolve spontaneously.[158] A moderate-sized prospective study following 169 patients over 6 months demonstrated that no children with persistent runny nose developed severe clinical symptoms or complications of CRS.[30] Data regarding specific medical treatment for CRS in children are very limited. The levels of evidence for each treatment are summarized in the EPOS 2012 document[2] and shown in **Table 24.4**.

While antibiotics have a modest overall benefit in the management of short-term RS symptoms, no such benefits have been demonstrated in the long term for children with CRS in one study.[159] No studies have demonstrated conclusive benefits of topical steroids in children with CRS, although a number of studies have demonstrated significant benefits in rhinitis, such that the EPOS consensus supports their use in paediatric CRS, albeit with little supporting evidence.[2] Nasal steroids in asthmatic patients with CRS may also reduce bronchial hyper-reactivity.[140] Saline douching with normal[160] or hypertonic saline[161] has some demonstrable efficacy in CRS, and may also improve parallel asthma symptoms,[162] but antral washouts are not recommended, with little evidence to support them. Treatment of active gastro-oesophageal reflux is also believed to improve CRS symptoms in patients affected by both conditions.[133, 163]

SURGICAL MANAGEMENT

Adenoidectomy

The role of the adenoids in the pathogenesis of paediatric rhinosinusitis remains uncertain, but adenoidectomy is known to improve symptoms in at least half of young children with CRS.[2] Whether the most important factor is the presence of the adenoids *per se*, their size or related bacterial colonization and inflammation (adenoiditis) is unclear, but there is likely to be a degree of heterogeneity in this context among young children with CRS. Nasal obstruction, snoring and hyponasal speech occur more often in children with adenoid hypertrophy while symptoms of rhinorrhoea, cough, headache, signs of mouth breathing, and abnormalities on anterior rhinoscopy occur as frequently in children with chronic rhinosinusitis as in children with adenoid hypertrophy.[164] In one study, antibiotic-resistant bacteria were found on culture of adenoid tissue in 56% of children undergoing adenoidectomy for hypertrophy plus otitis media with effusion and CRS, compared to 22% undergoing adenoidectomy purely for hypertrophy without those complications.[165] In another study, no significant correlation was found between the size of the adenoid and the presence of purulent secretions in the middle meatus on fibreoptic examination in 420 children aged 1–7 years. There was, however, a very significant correlation between the size of the adenoid and the complaints of mouth breathing and snoring.[166]

Endoscopic sinus surgery

Functional endoscopic sinus surgery (FESS) is a common intervention in adults with CRS, but its role in the management of paediatric CRS remains controversial. Certainly, conservative measures, initial medical management and adenoidectomy should be considered first, and where appropriate other underlying conditions should be excluded, before FESS is undertaken. Surgical management decisions will also be influenced by the presence of underlying pathology such as CF, PCD and AFS.

Importantly, washout procedures which were previously commonly undertaken (antral washouts, inferior meatal antrostomy and Caldwell Luc procedures) are ineffective and not recommended in this context.[1, 66, 67, 167, 168]

Absolute indications for FESS in children are the following:[69]

- complete nasal obstruction in cystic fibrosis due to massive polyposis or due to medialization of the lateral nasal wall
- orbital abscess
- intracranial complications

TABLE 24.4 Treatment evidence and recommendations for children with chronic rhinosinusitis (reproduced with permission[2])

Therapy	Level	Grade of recommendation	Relevance
Nasal saline irrigation	Ia	A	Yes
Therapy for gastro-oesophageal reflux	III	C	No
Topical corticosteroid	IV	D	Yes
Oral antibiotic long term	no data	D	Unclear
Oral antibiotic short term <4 weeks	Ib(–)[#]	A(–)*	No
Intravenous antibiotics	III(–)[##]	C(–)**	No

[#] Ib (–): Ib study with a negative outcome; *A(–): grade A recommendation **not** to use; [##]III(–): level III study with a negative outcome; **C(–): grade C recommendation **not** to use.

- antrochoanal polyp
- mucocoeles or mucopyocoeles
- fungal rhinosinusitis.

For other cases, where CRS symptoms persist despite optimal medical management, FESS may also be considered[1, 2] and can be limited to uncinectomy, partial ethmoidectomy and opening of the bulla and/or maxillary antrostomy.

In terms of demonstrable benefits, a small number of studies have shown improvements after FESS in children with CRS. A metanalysis of eight published articles (832 patients) showed positive outcome rates of 88–92%. The average combined follow-up was 3.7 years.[169] This concluded that FESS is a safe and effective treatment for CRS which is refractory to medical treatment. Other studies have produced similar results.[170–172] FESS is unlikely to be successful in very young children[173] and its efficacy is reduced if the child is exposed to tobacco smoke.[174] Disease duration prior to surgery does not affect outcome.[175] No obvious long-term differences in facial growth have been demonstrated in children with CRS undergoing FESS rather than those managed conservatively.[172]

Overall, therefore, FESS is likely to be beneficial in selected cases of paediatric CRS, but should be considered only after a period of medical management (and/or adenoidectomy) and exclusion of underlying pathologies. When undertaken, FESS should be limited in most circumstances, and typically avoided in very young children.

KEY POINTS

- Paediatric rhinosinusitis is extremely common.
- Evidenced based management has been presented in the literature, for example in the EPOS and ICARS documents.
- The characteristic features are rhinorrhea and nasal obstruction, often in conjunction with a cough and systemic upset in acute forms.
- Most cases of acute rhinosinusitis result from viral upper respiratory tract infections and some have an additional bacterial component, with a variety of common organisms implicated (typically gram positive).
- The majority of cases are self-limiting, some require treatment with antibiotics and very few result in complications.
- The possibility of orbital, intracranial and systemic sepsis should always be considered in children with rhinosinusitis, particularly in cases with pronounced symptoms and systemic derangement. This should prompt immediate investigation and specialist management.
- Chronic rhinosinusitis is also common. Many cases are exacerbated by adenoidal hypertrophy, and other anatomical factors are less commonly involved. Underlying inherited conditions such as cystic fibrosis and primary ciliary dyskinesia should also be considered in resistant cases.

CHAPTER 25

LACRIMAL DISORDERS IN CHILDREN

Caroline J. MacEwen and Paul S. White

SEARCH STRATEGY AND EVIDENCE BASE

PubMed MeSH searches were performed combining the terms lacrimal and disorders. Several thousand articles were identified, almost all too specific in context to guide this short overview chapter.

INTRODUCTION

The lacrimal system consists of a secretory portion and a drainage system. The secretory portion is made up of the lacrimal and accessory lacrimal glands which, together with the Meibomian glands and the goblet cells, secrete the components of the tear film. The accessory lacrimal glands produce basal tear secretion, and the lacrimal gland is largely responsible for reflex tearing in response to noxious or emotional stimuli. The drainage system consists of the lacrimal puncta, canaliculi, lacrimal sac and nasolacrimal duct (Figure 25.1). This active system pumps tears from the conjunctival sac into the inferior meatus of the nose. Clinical problems with the lacrimal system in children usually relate to the reduced drainage of tears. The underproduction of tears, causing dry eyes, is rare but more serious due to the potential for sight-threatening consequences.

ANATOMY

The lacrimal gland is an exocrine gland that sits in the anterior aspect of the supratemporal orbit. The ducts of the gland open onto the conjunctiva in the superior fornix. Embryologically the lacrimal gland develops from ectoderm that is supported by embryonic skull cap mesoderm. The lacrimal gland continues to grow up to the age of 4 years. Basal tearing is present in infants from birth, and reflex tearing begins at any time from birth to several months of age.[1] The lacrimal outflow system develops between the embryonic maxillary process and the lateral nasal process from a cord of surface ectoderm. By the end of the first trimester, this tissue begins to canalize and the nasolacrimal duct opens into the inferior meatus of the nose just before or after term birth. There may be a failure of this canalization process at any part of the system, but this is most frequent at the lower end.[2]

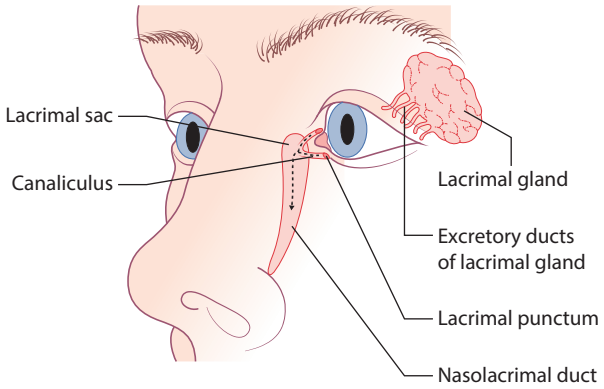

Figure 25.1 The lacrimal system, comprising the lacrimal gland, the lacrimal puncta, canaliculi, lacrimal sac and nasolacrimal duct.

Tears are actively pumped through the outflow system from the puncta and canaliculi and on into the lacrimal sac. This sits in the bony lacrimal fossa, separated from the middle meatus of the nose by the maxilla and lacrimal bone. The lacrimal sac extends superiorly under the medial canthal ligament as its fundus. The nasolacrimal duct exits from the lower end of the sac and passes in a downward, lateral and posterior direction. The duct is surrounded by bone in its upper part but becomes membranous inferiorly and opens into the medial wall of the inferior meatus of the nose through Hasner's valve. This can be located endoscopically in the inferior meatus approximately 1 cm posterior to the nasal spine.

DRY EYES IN CHILDREN

Children with dry eyes present with irritable, gritty eyes, which may be diffusely injected. On examination there is a reduced tear meniscus with punctate keratopathy, particularly affecting the interpalpebral zone. Staining occurs with fluorescein dye.

Congenital alacrima, or hyposecretion of tears, is rare. This may be due to absence of the lacrimal gland or to the lacrimal gland being ectopic. Alacrima may be associated with systemic conditions such as Allgrove syndrome (familial alacrima, achalasia of the cardia and glucocorticoid deficiency), anhydrotic ectodermal dysplasia and Riley–Day syndrome (familial dysautonomia),

Acquired tear insufficiency may be due to pathology of the lacrimal gland, causing failure of tear production, or to conjunctival damage, leading to ductule obliteration. The gland may be damaged by Epstein–Barr infection, as the result of HIV infection, or in patients following bone marrow transplantation (often associated with graft versus host disease). Sjögren's syndrome is rare in children; it can be a primary autoimmune event or secondary to rheumatoid arthritis or systemic lupus erythematosus (SLE). Children with Sjögren's syndrome often have lacrimal gland involvement, and they may have recurrent parotid gland swelling and salivary gland involvement. Sjögren's should be considered in any child with recurrent parotitis, keratoconjunctivitis sicca, and early tooth decay due to xerostomia.[3]

Isotretinoin treatment for acne can cause dry eyes in adolescence. This is usually reversible at cessation of the drug. Treatment of dry eyes involves copious use of artificial tears and temporary or permanent punctal occlusion in severe cases.

LACRIMAL TUMOURS AND GRANULOMAS

Lacrimal tumours are extremely rare in children. Orbital 'pseudotumour' (the preferred name is now idiopathic orbital inflammatory disease), causing painful swelling, is rare but may affect the lacrimal gland.[4] It is a non-infective inflammatory disease of unknown aetiology that occurs in the orbit and responds to steroids. Malignant epithelial tumours, including mixed-cell adenocystic and other carcinomas, have been recorded in childhood.[5] Lacrimal gland enlargement is also found in conditions such as sarcoidosis and leukaemia. Prolapse of the lacrimal gland, which is commonly bilateral, may present as a subconjunctival mass in the upper outer fornix. This may occur with craniofacial anomalies due to reduced orbital volume and increased orbital pressure.

Figure 25.2 Congenital dacryocystocele. A bluish swelling is seen below the medial canthal tendon. It can present as nasal obstruction.

Dacrocystocoele is a congenital swelling located at the medial canthus due to trapped fluid inside the lacrimal sac and nasolacrimal duct.[6] This usually presents as a tense, blue, non-pulsatile swelling below the medial canthus that is evident at birth (**Figure 25.2**). Congenital dacryocystocoele must be differentiated from a meningoencephalocoele, a meningocoele, a midline nasal dermoid cyst or a capillary haemangioma. If there is any doubt, an MRI scan is helpful in identifying the dilated sac and nasolacrimal duct and in excluding other pathology. Routine imaging, however, is not necessary and the diagnosis is usually made clinically.

Treatment of a dacryocystocoele involves observation during the first 2 weeks of life, during which time most will improve spontaneously. If it has not settled by this stage or if acute dacryocystitis or respiratory difficulties develop, then surgical treatment is required. A skin scar can be avoided by drainage of the dacryocystocoele into the nose using an endoscopic approach.

CONGENITAL NASOLACRIMAL DUCT OBSTRUCTION

Congenital nasolacrimal duct obstruction (CNLDO) is clinically evident in up to 20% of infants, the vast majority of which become symptomatic with epiphora during the first month. The natural history is to spontaneously resolve with maturation (**Figure 25.3**).[7–9] Spontaneous resolution is rapid during the first year of life and continues, at a reduced rate, beyond this into childhood.[10, 11] CNLDO represents a delay in maturation of the lacrimal drainage system where it enters the nose, resulting in persistent membranous obstruction or stenosis (**Figure 25.4**)

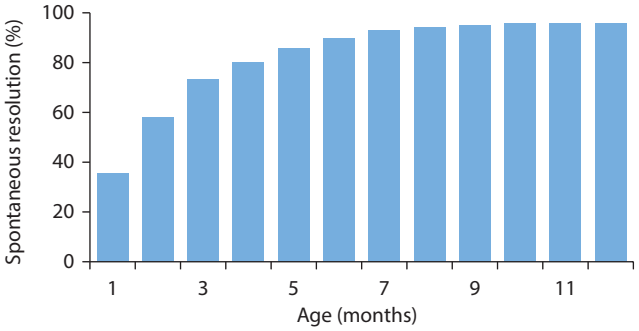

Figure 25.3 The rate of spontaneous resolution of nasolacrimal duct obstruction in 974 infants with congenital nasolacrimal duct obstruction as a function of age in months (adapted from MacEwen and Young[9]).

at the valve of Hasner. This should be differentiated from a dacryocystocoele.

Although usually an isolated abnormality, CNLDO may be more frequent in certain conditions, such as EEC syndrome (ectrodactyly, ectodermal dysplasia, clefting) branchio-oculo facial syndrome, craniometaphyseal or craniodiaphysial dysplasias, Down syndrome, lacrimo-auriculo-dento-digital (LADD) syndrome, and the CHARGE association.

On examination there is an increased tear meniscus and there may be stickiness or crusting on the lashes. A mucocoele may develop: the contents can be expressed into the conjunctival sac.

A fluorescein disappearance test (FDT) should be performed on children with epiphora as it provides objective evidence to support a diagnosis of lacrimal outflow obstruction.[12]

Treatment of congenital nasolacrimal duct obstruction

Congenital nasolacrimal duct obstruction has a very high rate of spontaneous resolution, so observation is recommended until the child is at least 1 year old. Under 1 year of age, probing is no better than observation and is generally not recommended. Between 12 and 24 months of age, the long-term results of probing and observation are the same but resolution is quicker with probing. Hence, most surgeons would recommend intervention some time after the first year of life.[10, 13–17]

Probing should be carried out in a stepwise fashion, identifying the patency or obstruction of each area between the puncta and the end of the nasolacrimal duct. The first stage of probing is a blind procedure and depends on awareness of resistance to the probe as it passes through the system. Thereafter the use of a 2.7 mm or 3.0 mm nasal endoscope will permit a direct view of the lower end of the nasolacrimal duct which assists in the diagnosis and management.[17, 18] The nose is first prepared with vasoconstrictor solution then a nasal endoscope is introduced into the inferior meatus after infracture of the inferior turbinate with a Freer elevator. This manoeuvre itself is often therapeutic as it opens up a narrow inferior meatus and may stretch a stenotic ostium.[19] Finally, fluorescein appearance is checked by syringing: stained fluid

Figure 25.4 Stenotic flow of fluorescene flush through the valve of Hasner within the inferior meatus of the right nasal cavity.

should be gently syringed into the system from above and observed through the nasendoscope.

The system should then be probed via the upper canaliculus using the smallest probe available (usually a Bowman's size 0000), which can be observed via the nasendoscope entering the inferior meatus through the valve of Hasner (see **Figure 25.4**). In cases of atresia the membrane can be incised endoscopically in the inferior meatus using a phaco knife. Unsuccessful probings can occur when the probe creates a false passage by missing the valve of Hasner, and either carries on in a submucosal plane to the floor of the nose or enters the meatus through a false and usually ineffective passage. Distal bony atesia of the duct is rare but will usually be rectified by conversion of the procedure to an endoscopic dacryocystorhinostomy (DCR).

PHYSIOLOGICAL (FUNCTIONAL) EPIPHORA

Functional epiphora is persistent watering despite a clear, patent, free-flowing syringing, observed endoscopically in the inferior meatus, with no resistance felt on probing. All other causes of lacrimation or epiphora must be eliminated. The FDT demonstrates delay. The cause of functional epiphora is probably physiological pump failure but such children may have an upper respiratory cause, such as large adenoids, and a careful history should be taken regarding nasal symptoms.

COMPLEX ABNORMALITIES OF THE OUTFLOW SYSTEM

Complex abnormalities of the canaliculi or the proximal nasolacrimal duct become a commoner cause of persistent epiphora in older children, as the simpler abnormalities settle spontaneously. These abnormalities may be very complex, especially in children with abnormal facial skeletons.[20]

A major advantage of endoscopic probing over 'blind' probing is that the common causes of failure can be

identified and treated at the first probing, improving the success rate of the procedure.[18] If endoscopic probing was not performed on the first occasion, this approach is useful in reprobings as it will identify the most frequent causes of failure and permit appropriate treatment.[18] Another option is intubation of the system with silicone tubes;[21] but intubation carries the risk of damage to the canaliculi, may be unnecessary (e.g. in functional cases), and is no more effective than endoscopic probing in repeat cases.[22] Children with upper nasolacrimal obstruction can be treated by endoscopic dacryocystorhinostomy (DCR) which offers the advantage of direct visualization of the common canaliculus at entry into the lateral wall of the lacrimal sac where distal occlusion of the common canaliculus may be amenable to a stenotomy.

Possible complications of intubation include cheesewiring through the canaliculi, dislocation superiorly or inferiorly, infection, and scarring of any part of the drainage system.[23] The optimum time to leave tubes in place is not known, and anywhere between 1 and 6 months is recommended.[23] Tubes should be removed under general anaesthetic via the nose to prevent aspiration of the tube. This system is then syringed with fluorescein under endoscopic control to confirm patency. Balloon catheter dilatation of the lacrimal system is a possible alternative to intubation in patients with failed probing.[24]

DACRYOCYSTORHINOSTOMY

Children rarely require a dacryocystorhinostomy (DCR), but may do so for persistent epiphora despite probing, for complex congenital abnormalities of the lacrimal outflow apparatus such as bony atresia, those involving the upper nasolacrimal duct, or for acquired disease usually caused by infection or trauma.[25] External and endoscopic routes are possible, and excellent success rates, comparable to those of adult DCRs, have been reported for both.[26, 27]

The availability of microdrill techniques has led to increased popularity of the endoscopic techniques which enable wide sac exposure and flap creation without a facial skin scar.

CONGENITAL FISTULAE OF THE LACRIMAL OUTFLOW SYSTEM

Fistulae of the lacrimal system are rare anomalies in which tracts open onto the skin directly from the puncta, canaliculi, lacrimal sac or nasolacrimal duct. They may appear as double puncta, or appear in the region of the medial canthus. They usually pass unnoticed as they are non-functioning and should be left untreated unless they allow flow of tears onto the face or result in epiphora (which is rare).

PUNCTAL AND CANALICULAR ABNORMALITIES

Failure of the proximal end of the lacrimal drainage system to canalize may result in punctal stenosis or atresia. This is often asymptomatic, especially if only one punctum is abnormal. Narrow puncta should be dilated with a 'Nettleship' lacrimal dilator. Membranous obstruction should be pierced with a needle and dilated. These cases do very well but are often associated with distal abnormalities and a syringing should always be performed.

Overall, abnormalities proximal to the sac result in surprisingly few symptoms. Agenesis should be suspected if the papilla is not readily obvious.[28] If only one punctum is missing, syringing via the other one detects the extent of the damage. Surgery to construct these areas is specialized. Retrograde probing from an external DCR incision may be attempted through the sac; otherwise, a Lester Jones canalicular tube is required. This type of surgery may be left until the child is in their teens when referral to a specialist should be made.

ACQUIRED CONDITIONS OF THE LACRIMAL DRAINAGE APPARATUS

Acute dacryocystitis may occur as a complication in non-patent nasolacrimal systems or as a primary event in a patent system. This is particularly common in infants with a dacryocystocoele.[29] Treatment comprises prompt intervention with intravenous antibiotics as retrobulbar abscesses may occur. Cultures should be taken of any pus or discharge that can be expressed through the punctum. Probing should not be performed as damage to the congested epithelium may cause false passage formation and lead to orbital cellulitis and fistula formation.[30] Skin incisions should not be made during the acute phase as an external fistula may occur. If a mass remains after resolution or a pyocoele has developed, evacuation can be performed through the skin with a needle through the lower pole of the sac or by urgent endonasal DCR if the pus is found to be inspissated or loculated.

Acquired nasolacrimal duct obstruction may be caused by facial trauma, diseases of the nose or paranasal sinuses – especially chronic allergic rhinitis – or persistent upper respiratory tract infections. These are more common in older children and adolescents.[31] Rarely, acquired obstruction may herald a more sinister cause such as fibrous dysplasia, cranial metaphysial or cranial diaphysial dysplasia, or tumour formation. Treatment should be aimed at the underlying cause.

The commonest causes of watery eyes in children are listed in **Box 25.1**.

BOX 25.1 Causes of watery eyes in children

Excess tear production (lacrimation)	Drainage failure (epiphora)
Allergic rhinitis	Congenital nasolacrimal duct obstruction
Upper respiratory tract infection	Skeletal and sinus abnormalities
Epiblepharon	Lid malposition
Subtarsal foreign body	Punctal malposition
Iritis	Punctal occlusion
Corneal abrasion/ulceration	Anomalous drainage system
Conjunctivitis	
Glaucoma	

FUTURE RESEARCH

- Knowledge of the aetiology and best treatment choices for proximal CNLDO are less well developed.
- While surgery is almost invariably successful for treating distal block, the management of proximal obstruction remains challenging.
- The increased application of endoscope and microendoscope technology in the future may offer better diagnostic and therapeutic options for resistant cases of CNLDO.

KEY POINTS

- Congenital nasolacrimal duct obstruction (CNLDO) is common, being present in up to 20% of neonates.
- The majority of cases of CNLDO resolve spontaneously in infancy.
- Epiphora persisting in the second year of life may benefit from intervention.
- Endoscopic-guided probing is the investigation of choice.
- Underproduction of tears causing dry eyes is rare but more serious due to the potential threat to vision.

CHAPTER 26

THE ADENOID AND ADENOIDECTOMY

Peter J. Robb

SEARCH STRATEGY

Data in this chapter may be updated by searches of The Cochrane Library, Medline, Google Scholar and PubMed using the keywords: adenoid, adenoidectomy and children. References from selected articles were reviewed after reading the abstract and included where relevant. The evidence in this chapter is mainly level 2/3/4, with some level 1 evidence.

INTRODUCTION

Santorini described the nasopharyngeal lymphoid aggregate or 'Luschka's tonsil' in 1724. Wilhelm Meyer coined the term 'adenoid' to apply to what he described as 'nasopharyngeal vegetations' in 1870. The adenoid forms part of Waldeyer's ring of lymphoid tissue at the portal of the upper respiratory tract. In early childhood this is the first site of immunological contact for inhaled antigens.

Historically, the adenoid has been associated with upper airway obstruction, as a focus of sepsis, and more recently with the persistence of otitis media with effusion.

DEVELOPMENT OF THE ADENOID

Lymphoid tissue can be identified at the 4- to 6-week gestational period, lying within the mucous membrane of the roof and posterior wall of the nasopharynx. The adenoid is clearly identifiable during the third month of gestation. Lymphoid tissue of the adenoid may extend to the fossa of Rosenmüller and to the Eustachian tube orifice as Gerlach's tonsil. The membrane is covered with stratified squamous epithelium. The adenoid receives a rich arterial supply from branches of the facial and maxillary arteries and the thyrocervical trunk. Venous drainage is to the internal jugular and facial veins. Lymphatic drainage is to the retropharyngeal lymph nodes and upper deep cervical nodes, particularly the posterior triangle of the neck. Nerve supply is from sensory branches of the glossopharyngeal and vagus nerves.[1]

The adenoid is visible using magnetic resonance imaging (MRI) from the age of 4 months in 18% of children.[2] At 5 months of age, the adenoid could be identified in all of 290 children studied. Growth continues rapidly during infancy and plateaus between 2 and 14 years of age. Regression of the adenoid occurs rapidly after 15 years of age in most children. The adenoid is at its relative largest in relation to the volume of the nasopharynx in the 7-year-old age group.[3] Clinical symptoms are more common in a younger age group, due to the relative small volume of the nasopharynx and the increased frequency of upper respiratory tract infections.

IMMUNE FUNCTION OF THE ADENOID

The function of the lymphoid tissue of Waldeyer's ring is to produce antibodies. The adenoid produces B-cells, giving rise to IgG and IgA plasma cells. Exposure to antigens via the mouth and nose is an important part of natural acquired immunity in early childhood. The adenoid appears to have an important role in the development of 'immunological memory' in younger children.[4] Removal of the adenoid in early childhood may be immunologically undesirable.[5] Evidence supports the concern that early adenoidectomy produces a detectable negative effect

on the development of serum IgG antibodies, resulting in impaired immunity to pneumococcus.[6]

In children aged 4–10 years, adenotonsillectomy does not appear to cause significant immune deficiency, although a slight decrease in IgG, IgA and IgM levels was found in the post-operative period 4–6 weeks after surgery.[7] The authors concluded that this represented a compensatory response of the developing immune system following a reduction of chronic antigen stimulation. Specific reduction in IgG may represent a reduction in antigenic stimulation. There appears to be no decrease in IgE after adenoidectomy.[8, 9]

The evidence that immune status is compromised by removal of the adenoid alone is inconclusive, as studies generally include children also having tonsillectomy.[10]

PATHOLOGICAL EFFECTS OF THE ADENOID

The adenoid may be implicated in upper respiratory tract disease due to partial or complete obstruction of the nasal choanae or as a result of sepsis. Pathological manifestations include rhinitis, rhinosinusitis, otitis media and otitis media with effusion. Adenoiditis, acute or chronic, is considered by some to be a related but distinct infective entity.[11]

Otitis media with effusion

The benefit of adenoidectomy in the management of otitis media with effusion (OME) has traditionally been ascribed to the relief of anatomical obstruction of the Eustachian tube.[12] While this may be a contributory factor, it is clear that adenoid size and physical obstruction alone cannot account for the benefit following adenoidectomy when the adenoid is small.[13] Adenoid size in children with and without OME is not significantly different. It is likely that recurrent acute or chronic inflammation of the adenoid and increased bacterial load, particularly of *Haemophilus influenzae*,[14, 15] results in squamous cell metaplasia, reticular epithelium extension, fibrosis of the interfollicular interconnective tissue and reduced mucociliary clearance in children with OME compared to those without OME.[16] These changes increase bacterial adherence, contributing to the development of a 'biofilm' infection resulting ultimately in middle ear effusion. (A biofilm infection may be defined as 'a structured community of bacterial cells enclosed in a self-produced polymeric matrix and adherent to an inert or living surface'.[17, 18]) Evidence from the MRC TARGET (Trial of Alternative Regimens in Glue Ear Treatment) study supports consideration of 'adjuvant' adenoidectomy in children over the age of 3 who are undergoing insertion of ventilation tubes (grommets)[19] (see Chapter 13, Otitis media with effusion).

RECURRENT ACUTE OTITIS MEDIA

A Cochrane intervention review concluded that adenoidectomy could not be recommended for the management of acute otitis media.[20] Randomized controlled trials of the management of recurrent acute otitis media have shown adenoidectomy was not effective in reducing episodes of infection in children younger than 2 years during the follow-up periods of 7–24 months after surgery.[21, 22] It is likely that a partial maturational selective IgA deficiency is a contributing factor in these 'otitis-prone' children.[23] Low-dose prophylactic antibiotic treatment is preferred to adenoidectomy in this group as a means of preventing recurrent acute otitis media and sequelae of infection until maturation of the immune system occurs naturally.[24]

Upper airway obstruction and sleep-disordered breathing

Sleep-disordered breathing in childhood is considered in detail in Chapter 27, Paediatric obstructive sleep apnoea. The prevalence of severe sleep disturbance in children due to upper airway obstruction is estimated to be approximately 1%, with a peak incidence between 3 and 6 years of age, and an equal sex incidence.[25, 26]

Airway obstruction due to adenoidal hypertrophy may produce depressed arterial PaO_2 and elevated $PaCO_2$ levels, which return to normal after adenoidectomy.[27] The respiratory improvement following adenotonsillectomy also results in a significant increase in serum insulin-like growth factor-1 (IGF-1),[28] accounting in part for the frequently observed growth spurt following surgery. Accumulating evidence suggest that habitual snoring, falling short of obstructive sleep apnoea may result in neurobehavioural morbidity, poor academic performance and hyperactive behaviour.[29, 30]

There is widespread recognition of sleep apnoea in childhood[31] and the acceptance of the benefits of adenotonsillar surgery in these children, with documented improvement in respiratory function following adenotonsillectomy.[32] In a prospective study of 40 children undergoing adenoidectomy, with or without tonsillectomy, for upper airway obstruction, the radiographic estimate of the adenoid size correlated highly with the improvement in polysomnographic scores following surgery. No significant correlation between tonsil size and grade of obstructive sleep apnoea was demonstrated.[33] Nevertheless, a Cochrane review of adenotonsillectomy for obstructive sleep apnoea found no randomized trials addressing the criteria required to nor the efficacy of surgery in managing obstructive sleep apnoea syndrome (OSAS) in children.[34]

Rhinosinusitis

In childhood, the adenoid is implicated in rhinosinusitis, acting as a reservoir for pathogenic bacteria.[35] In a retrospective study of 48 children with chronic sinusitis undergoing adenoidectomy or adenotonsillectomy, improvement was reported in the majority following surgery, and only three children subsequently required functional endoscopic sinus surgery.[36] A prospective study of children with recurrent rhinosinusitis showed that adenoidectomy was effective in abolishing infective episodes of infection, and that few children went on to require functional

endoscopic sinus surgery[37] (see Chapter 24, Rhinosinusitis and its complications).

Olfaction

Adenoidal hyperplasia may reduce olfactory sensitivity and, in particular, retronasal smell and taste, which improves following adenoidectomy.[38] It is, however, unlikely that physical obstruction of the airway alone impairs olfaction, and changes in the olfactory epithelium are a likely factor.[39] Where partial or total anosmia is reported, with no evidence of adenoidal hyperplasia, or failing to resolve after adenoidectomy, further detailed investigation is required to exclude congenital or hereditary causes for child's poor or absent sense of smell.[40]

Neoplasia

Unsuspected neoplasia of the adenoid (and tonsils) in childhood is rare. Non-Hodgkin lymphoma was reported in a series of six children.[41] Atypical lymphadenopathy, with persistent and asymmetric enlargement of the tonsils and adenoid, in the absence of infection are suspicious and should prompt early imaging and biopsy. Presentation is often assumed to be due to the more common infective and obstructive manifestations of adenotonsillar disease so diagnosis is frequently delayed. Consider lymphoma of the adenoid as part of a post-transplantation lymphoproliferative disorder when symptoms of nasal obstruction develop.[42]

ASSESSMENT AND MANAGEMENT

Clinical history

The history should form part of a full paediatric ENT history with special attention to symptoms of middle ear disease and nasal obstruction. Specific questions regarding sleep disturbance, eating and atopic symptoms are important. A family history of atopy may be relevant. A full history of medication, prescribed, over-the-counter and alternative or complementary, is important. In children in whom adenoidectomy is being considered, it is essential to positively exclude a history or family tendency of unusual bleeding or bruising, as a routine clotting screen may not confirm mild von Willebrand disease. In children with Down syndrome, consider potential atlantoaxial instability and cardiac abnormalities.

Clinical examination

Assessment of the external nose should be made prior to anterior rhinoscopy. In particular, look for a skin crease in the supratip region that may indicate frequent nose rubbing from symptoms of rhinitis. Simple anterior rhinoscopy in young children may be carried out using a halogen light otoscope with a large speculum. This is generally better tolerated than examination with a Thudichum speculum.

Assessment of the nasal airway may be made with a cold Lack tongue depressor or large laryngeal mirror. Posterior mirror rhinoscopy is not usually possible in children, but many will tolerate nasendoscopy,[43] using a flexible paediatric endoscope and topical intranasal local anaesthetic/vasoconstrictor spray, such as Co-phenylcaine. When examining children, topical cocaine must not be used.

In children, where adenoidectomy is the sole surgical procedure indicated, an assessment of the adenoid should be made prior to the decision to operate. Nasendoscopy is a highly accurate method to assess adenoidal status in an outpatient setting (**Figure 26.1**).

When endoscopy is not tolerated, assessment of adenoid size with lateral soft-tissue radiograph of the nasopharynx is helpful and correlates well with endoscopic assessment of adenoid size.[44, 45]

In children undergoing another surgical procedure, the adenoid size can be assessed per-operatively.[46] The adenoid can be classified, based on size and obstruction (**Table 26.1**).[47] Nasendoscopy of the nasopharynx to assess adenoid size at the time of surgery is probably the gold standard, while mirror examination underestimates choanal occlusion, and palpation is a poor measure of adenoid hypertrophy.[48]

Where the indication for adenoidectomy is OME rather than obstruction, the size of the adenoid is not relevant as

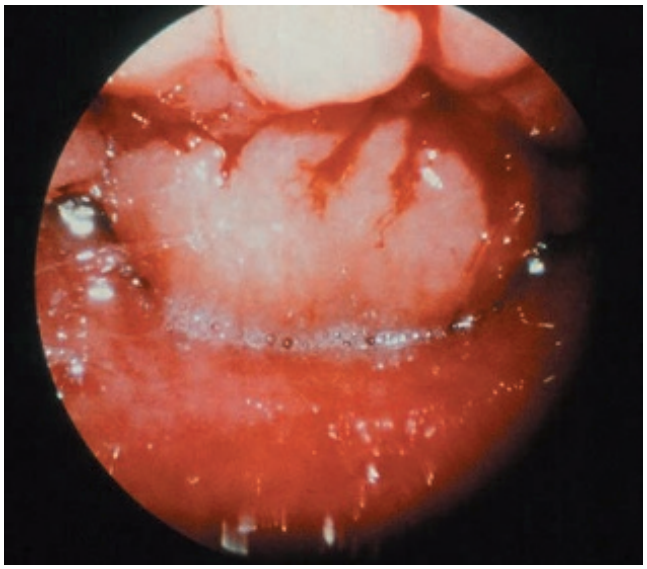

Figure 26.1 Endoscopic view of the adenoids.

TABLE 26.1 Clinical grading of adenoid size (reprinted from Clemens et al.,[47] with permission from Elsevier)

Grade	Description
Grade I	Adenoid tissue filling one-third of the vertical portion of the choanae
Grade II	Adenoid tissue filling from one-third to two-thirds of the choanae
Grade III	From two-thirds to nearly complete obstruction of the choanae
Grade IV	Complete choanal obstruction

an indication for removal (see Chapter 13, Otitis media with effusion).

While acoustic rhinomanometry is a useful research tool[49] and MRI provides extremely accurate volumetric estimation of the adenoid, these investigations are not applicable in clinical practice.

Pre-operative investigations

Routine pre-operative investigations are not indicated prior to adenoidectomy for children who are ASA grade 1 or 2.[50] Specific investigations for sickle-cell disease, thalassaemia, Down syndrome and congenital heart disease are indicated as appropriate. Management of type 2 diabetes mellitus should follow local paediatric guidelines for children with diabetes undergoing elective surgery.

MEDICAL TREATMENT FOR THE ADENOID

Traditionally, surgery and watchful waiting were the only options for symptomatic adenoid disease. There is now a reasonable amount of evidence that topical nasal steroid sprays can cause reduction in adenoid size with improvements in the presence of middle ear fluid, audiometric thresholds, nasal obstruction, rhinorrhoea, cough, snoring and sleep apnoea. This evidence comes from meta-analysis of a number of randomized controlled trials, although the trials themselves were judged to be of poor quality and further, better-quality studies are required.[51] Topical nasal steroids will probably find a role in clinical practice, although at present that role is unclear.

ADENOIDECTOMY

Adenoidectomy with or without tonsillectomy and/or insertion of ventilation tubes is one of the most frequently performed surgical procedures in children.

In the UK, blind curettage adenoidectomy continues to be the most used technique. Of these 79.2% use digital palpation and blind curettage, while only 8.1% use suction coagulation under direct vision.[52] It is surprising that curettage remains so popular, give the disadvantages of a blind procedure with unpredictable bleeding, poor access to choanal adenoid and risk of trauma to the Eustachian cushions. In contrast, suction diathermy affords direct vision with minimal blood loss[47] (mean 4 mL vs 50 mL), haemostasis and negligible risk of post-operative haemorrhage.[53] Suction diathermy is also effective in performing partial adenoidectomy, leaving a ridge of adenoidal tissue at the inferior part of the nasopharynx, reducing the risk of velopharyngeal insufficiency in those children where this is likely after removal of the adenoid.[54] Other direct vision techniques include Coblation® and microdebrider, which have the disadvantage of a high unit cost. KTP laser is associated with a high risk of nasopharyngeal stenosis.[55] This serious complication has not been reported in a small series using gold laser for adenoidectomy.[56] All single-use instrument techniques have the advantage of abolishing the potential risk of infection transmission.[57]

Of the direct-vision techniques, those with the largest clinical experience are the suction coagulator and the microdebrider. In a randomized controlled trial, the microdebrider was 20% faster than the curettage technique,[58, 59] but the suction coagulator is significantly cheaper than the microdebrider.[60] Coblation® is also suitable for adenoidectomy, with less blood loss and more complete adenoid removal,[61, 62] but cost limits it application to adenoidectomy as a sole procedure, while it is not a cost issue when tonsillectomy is performed using the same Coblation® wand.

A meta-analysis of suction coagulation adenoidectomy concluded that there was reduced intra-operative bleeding, reduced operative time, and a lower overall complication rate when compared to curette adenoidectomy.[63]

Where social and geographical factors allow,[64] and with appropriate surgical and anaesthetic techniques, pre-emptive fluid replacement, antiemetics and analgesia, the majority of children may be safely discharged home on the same day of surgery.[65, 66] Safe discharge home following adenoidectomy using the laryngeal mask airway within 20 minutes of surgery may be feasible but not preferable.[67]

COMPLICATIONS OF ADENOIDECTOMY

Bleeding

The reactionary haemorrhage rate, i.e. bleeding following adenoidectomy, within 6–20 hours of operation is reported as less than 0.7%.[68, 69] If bleeding is significant, early return to theatre and postnasal packing for haemostasis is the usual management. This study suggests that postnasal packing left *in situ* for 4 hours post-haemorrhage is as effective as packs left for 24 hours.[68] A small number of consultants in this questionnaire study (3/285) electively admitted children to an intensive care facility following postnasal packing and 4/285 routinely prescribed antibiotics. Increase in the use of direct-vision techniques and controlled haemostasis at the time of operation will make reactionary haemorrhage and the need for postnasal packing much less likely.

Secondary haemorrhage after adenoidectomy is rare. It may be due to bleeding from an aberrant ascending pharyngeal artery.[70] Unusual reactionary or secondary bleeding should raise the possibility of a clotting or coagulation defect. This requires specialist haematological investigation to confirm or exclude.

Dental trauma

Damage to the teeth during adenoidectomy may be accidental due to slippage of the gag or supports. Great care is needed, particularly if the secondary incisors have erupted: the teeth are large, but the mandible immature, and it is safer to use an adult gag, which will rest lateral to the incisors. It is customary to warn parents about damage

to teeth, but damage to the teeth will usually be considered indefensible. Where there are loose deciduous teeth, consent should be taken pre-operatively to remove these under anaesthetic to avoid the possibility of inhalation by the child during the operation or while recovering from anaesthesia.

Retained swab

If swabs are used, it is mandatory to confirm that the count is correct at the end of the operation before the gag is removed and the anaesthesia reversed. A swab may be retained either in the nasopharynx or in the laryngopharynx, hidden from the operator's view. While the early post-operative risk is of airway obstruction by a retained swab, late presentation months later with infection has also been reported.[71] Using direct-vision suction coagulation or Coblation® generally abolishes the need for swabs as haemostasis can be achieved during the procedure.

Nasopharyngeal blood clot

Blood may pool and clot in the nasopharynx during the procedure. The nasopharynx should be gently suctioned to clear any clot before removing the gag. Failure to do so may lead to the clot falling onto the larynx during recovery and causing potentially fatal acute airway obstruction ('coroner's clot'). Using a disposable rose-tipped sucker in the pharynx rather than a catheter via the nose reduces the risk of starting bleeding from the adenoid bed.

Infection

Infection in the nasopharynx following adenoidectomy is clinically uncommon, although many parents report foetor from their child in the week following surgery. Foetor is more common following suction adenoidectomy, and it is customary to prescribe a short course of antibiotics (e.g. azithromycin 10 mg/kg for 3 days post-operatively) to avoid this.[65] Rarely, retropharyngeal and mediastinal abscesses may occur as a result of trauma and secondary infection of the adenoid bed.[72] Post-operative chest infection in contemporary practice is uncommon.

Cervical spine

Non-traumatic atlantoaxial subluxation (Grisel syndrome) is rare, but it is recognized as a risk associated with adenoidectomy and tonsillectomy.[73] Early recognition is crucial in management, and post-operative torticollis should raise suspicion, leading to radiological investigation.[74] Overuse of diathermy must be avoided, either for removal of the adenoid or following curettage when used for haemostasis.[65] Minimum power settings for diathermy should always be used.[75]

Children with Down syndrome are at increased risk of atlantoaxial subluxation. Current evidence does not support routine pre-operative plain radiographs in asymptomatic children with Down syndrome. In any event, these are of limited value below the age of 3 years, at which age vertebral mineralization and epiphyseal development permit accurate radiographic visualization.[76] Special care of the child's neck during anaesthesia, surgery and recovery is essential.

Velopharyngeal dysfunction

Severe velopharyngeal incompetence is rare following adenoidectomy, estimated to occur in between 1:1500 and 1:10000 procedures. It may lead to significant problems with hypernasal speech and swallowing, severe enough to cause nasal regurgitation of fluids. It is mandatory to assess the palate and uvula for submucous cleft of the palate prior to surgery as adenoidectomy may unmask pre-existing palatal dysfunction.[77] Bifid uvula can be a marker of a submucous cleft, present in 59% of cases.[78] Using a direct-vision technique, it is possible to perform a partial adenoidectomy, clearing the choanal airway and superior nasopharynx, but leaving a rim of adenoid intact at the velopharyngeal junction, avoiding velopharyngeal insufficiency.[54]

Long-term velopharyngeal insufficiency is rare. Reconstructive surgery to correct hypernasal speech may be required if speech and swallowing are severely affected.[79]

Regrowth of the adenoid

A cross-sectional follow-up study of children after curettage adenoidectomy, 2–5 years after surgery concluded that 71% had no residual obstructing adenoid. However, the criterion for adenoid sufficient to cause nasal obstruction was tissue occupying more than 40% of the nasopharynx.[80] In a retrospective study of 3231 children, 1.6% required reoperation for recurrence of their symptoms following curettage adenoidectomy.[81] Direct-vision techniques are likely to minimize residual adenoid tissue and possible 'regrowth'.[63]

Death

Data separating the risk of death following adenoidectomy independent of tonsillectomy or general anaesthesia is limited. Expert reports from malpractice cases are the usual source of such data. Of 32 deaths related to bleeding following adenoidectomy and tonsillectomy, one followed direct vascular injury during adenoidectomy. In a review of malpractice cases from the United States, following tonsillectomy and adenoidectomy, during the period 1985–2006, 154 claims were identified.[82] Two deaths clearly followed infection secondary to aspiration of adenoid tissue. While not defined as adenoidectomy alone, four deaths were due to medication errors, route, dose or drug.[71] Following surgery in younger children with sleep-disordered breathing, special care should be exercised when prescribing opioid analgesics for both per-operative and discharge analgesia.[83] In those who are ultra-rapid metabolizers of codeine, toxic doses of morphine can develop, leading to fatal respiratory failure.

BEST CLINICAL PRACTICE

- ✓ It is no longer appropriate to combine adenoidectomy with tonsillectomy, unless there is a specific indication for adenoidectomy.
- ✓ Adjuvant adenoidectomy is effective as part of the surgical management of children over the age of 3 years with otitis media with effusion.
- ✓ Routine pre-operative investigations are not indicated prior to adenoidectomy for children who are ASA grade 1 or 2.
- ✓ Adenoidectomy under direct vision with single-use instrumentation – except the KTP laser – is more effective and safer than curettage.

FUTURE RESEARCH

For each of the following topics there is no evidence at level 1 currently available, and further studies are recommended.

- ➤ The role of topical nasal steroids in management of adenoid disease.
- ➤ Efficacy and morbidity of different techniques of adenoidectomy.
- ➤ Efficacy of adenoidectomy in the management of obstructive sleep apnoea in children.
- ➤ Efficacy of adenoidectomy in the management of chronic and recurrent acute sinusitis in children.
- ➤ The effects of adenoidectomy on the development of childhood immunity.
- ➤ The relationship between adenoidal hypertrophy and childhood rhinitis.
- ➤ The role of the adenoid in facilitating a biofilm infection in the upper respiratory tract.

KEY POINTS

- Adenoidal hyperplasia in childhood is common and self-limiting; mild symptoms of obstruction are not an indication for surgery.
- Significant obstructive symptoms, resulting in sleep-disordered breathing, short of obstructive sleep apnoea, may have signficant effects on daytime behaviour and cognitive function reversed by adenoidectomy.
- Adenoidectomy is effective as part of the surgical management of children with upper airway obstruction.
- Adenoidectomy may not be effective in the management of recurrent acute otitis media.

CHAPTER 27

PAEDIATRIC OBSTRUCTIVE SLEEP APNOEA

Steven Powell

SEARCH STRATEGY

Data in this chapter may be updated by a Medline search using the following keywords: sleep apnoea, tonsils, adenoids, sleep-disordered breathing, all child (0 to 18 years) in articles published in English. Abstracts were hand-searched and relevant articles were obtained and summarized.

HISTORY

Obstructive sleep apnoea in children existed for a long time without being widely recognized as a clinical syndrome. There were some exceptions to this. In 1889 Hill published an article in the *British Medical Journal* 'On some causes of backwardness and stupidity in children'.[1] There are a number of startling revelations in this work. Hill identified the neurobehavioural consequences of OSA:

> *'…children, the victims of nasal and pharyngeal obstructions, often suffer from headaches especially when engaged in study, and frequently evince marked inability to fix their attention on their lessons or work for any length of time…'.*[1]

Perhaps even more remarkably, he described the outcomes of treatment, recognizing that adenotonsillar surgery at the same time as treatment for glue ear resulted in neurobehavioural improvements over and above those expected for hearing improvement alone:

> *'I have been much struck by the fact that operations on children, undertaken for the relief of deafness associated with adenoidal growths, enlarged tonsils, and hypertrophic catarrhal conditions of the nose, have resulted in an immediate improvement in the mental acuteness of the patients as was altogether incommensurate with the often slight improvement in the sense of hearing.'*[1]

Many children who were being treated with adenotonsillectomies for various reasons from blocked noses to infections probably had unrecognized sleep apnoea. There had been some recognition of the cardiac complications of upper airway obstruction, but the first case series recognizing the syndrome of obstructive sleep apnoea was not published until 1976.[2] Guilleminault and colleagues described eight children with the night-time symptoms and the daytime consequences of obstructive sleep apnoea. It was the interest in this condition among the adult population that led to the recognition of the daytime symptoms in children. Six of the eight children underwent adenonsillectomy. Four of them had resolution of their symptoms, but two went on to have a tracheostomy.

Since then there has been growing interest in the condition and it has become the leading indication for adenotonsillectomy in young children.[3] The literature about the condition has expanded exponentially with over 2000 articles listed by Medline with relevance to paediatric sleep-disordered breathing in the last 3 years alone.

EPIDEMIOLOGY

Habitual snoring in children is quite common in the UK population, occurring in 12% of children.[4] Two large cross-sectional studies from the UK and Italy found the prevalence of obstructive sleep apnoea (OSA) to be 0.7–1.8%.[4, 5] In a German study looking at a community sample of children who went on to have polysomnography (PSG), the prevalence of primary snoring was found to be 6.1%.[6]

A large population-based cohort study with a wider remit had some questions geared towards mouth breathing, snoring and apnoeas. The Avon Longitudinal Study of Parents and Children (ALSPAC) studied 14 029 children. Nocturnal apnoeas always had a prevalence of 1–2% and were fairly steady throughout the first 6 years of the child's life. The prevalence of snoring always increased from 3–4% at the age of 1 year to a peak of 7–8% between the ages of 3 and 4. In terms of habitual snoring (which reflected snoring not being present all the time, but most), the prevalence rose from 10% at 1 year to 15% at 6 years. Habitual mouth breathing was present in up to 25% of children. Adenoidectomy reduced the risk of having sleep-disordered breathing by parental report in this study.[7]

NORMAL SLEEP

Paediatric sleep physiology is not completely understood, but what is clear is that a grasp of the basic elements is important to having a full understanding of the pathophysiology of sleep-disordered breathing.[8] Sleep is an essential human function and is part of the body's 'housekeeping' role, and good sleep is critical to normal daytime functioning. Sleep can be divided into phases of a cycle. There are phases of REM (rapid eye movement) sleep and nREM (non-rapid eye movement sleep). nREM sleep is divided into phases N1, N2 and N3. N3 is commonly described as 'slow wave' sleep. There is an orderly progression between the phases from N1 to N3 then REM sleep. The cycle in older children takes around 90 minutes. The proportion of time in slow wave sleep is higher at the beginning of the night and the proportion in REM sleep is higher at the end of the night. The proportion of time spent in REM sleep decreases from 50% as a newborn to 20% beyond the age of 4 years.[9] Premature babies and those up to 6 months of age can have central apnoeas, with cessation of breathing due to no respiratory effort, but it is rare for these to persist with any clinical significance beyond 6 months.[8]

Muscle relaxation occurs particularly during REM sleep, possibly as a protective mechanism to prevent sleep movements. The pharyngeal part of a child's upper airway is a tube with a soft collapsible wall held open only by active pharyngeal muscle tone. There can be relaxation of the pharyngeal constrictor muscles (hypotonia) and a narrowing of the airway at the pharyngeal level. A wide range of neural activity occurs during the sleep cycle which is critical to the consolidation and enhancement of memories within existing neural networks.[9]

DEFINITIONS

Obstructive sleep apnoea can be defined as 'a disorder of breathing during sleep characterized by prolonged partial upper airway obstruction and/or intermittent complete obstruction that disrupts ventilation during sleep and normal sleep patterns'.[10] **Primary snoring** is defined as noisy breathing (snoring) without obstructive apnoea, frequent arousals from sleep, or gas exchange abnormalities.[10] **Sleep-disordered breathing** is a term which can be used to describe both snoring and OSA.

PATHOPHYSIOLOGY

Pathophysiology of airway obstruction

It becomes clear from the key points in physiology that there are phases within sleep when children will be particularly at risk of airway compromise. REM sleep, with its hypotonia of the pharyngeal muscles, can lead to airway narrowing particularly at this point.

There are well-defined groups in which sleep-disordered breathing may occur. There may be overlap between the groups, but they can be considered individually.

Children with no underlying medical diagnosis who have adenotonsillar hypertrophy form the largest group overall.[11] Here the physical obstruction of the nasal airway by the adenoids and the oropharyngeal airway by the tonsils results in increased airway resistance. The peak incidence of OSA in this group is between the ages of 3 and 6 years when the adenoids and tonsils undergo hypertrophy.[11] The situation is more complex than simple obstruction by adenoid and tonsil hypertrophy as not all children with large lymphoid tissue have OSA reflecting variation between individuals in pharyngeal muscle tone.[11]

The second group reflects the increasing prevalence of obesity in the paediatric population.[12] This may be in a slightly older age group. It may occur in combination with adenotonsillar hypertrophy. The obstructive element is primarily caused by oropharyngeal crowding due to excess adipose tissue, but the full extent of the pathophysiology surrounding obesity is considerably more complex.[12]

In a third group of children the cause of OSA is multifactorial. Children with congenital abnormalities such as achondroplasia or craniofacial abnormalities have narrow pharyngeal airways which will predispose them to obstruction. In Down syndrome there is a combination of abnormally narrow upper airway and reduced pharyngeal muscle tone. **Up to two-thirds of children with Down syndrome have some form of sleep-disordered breathing and regular screening for OSA is advised.**[13]

Neurobehavioural consequences

Neurobehavioural clinical outcomes result from the disturbance to sleep from a number of mechanisms.[8] In the worst cases where there are desaturations, hypoxia may

play a role, but sleep fragmentation from repeated arousals can interfere with the neural pathways which would otherwise occur. Even in children who have no OSA and primary snoring alone, there has been a link to the slow wave activity changes of the EEG, which may reflect impaired restorative sleep function.[14] OSA has a profound impact on sleep and arousal patterns during the preschool years, when children are in a critical period for neurodevelopment.[15]

Inflammatory basis

There is an underlying inflammatory basis to OSA and there appear to be several biomarkers which measure this activity.

Children often have elevated levels of highly sensitive C-reactive protein (CRP). This is produced by interleukin activity in the liver. Some children seem to have a predisposition to this and in one study abnormal DNA methylation was found in patients with OSA and high CRP, and the abnormal methylation was strongly linked to the apnoea–hypopnoea index (discussed in 'Investigations' below).[16] This epigenetic discovery may lead to the basis of future prognostic or therapeutic advances.

High levels of CRP may enhance inflammation, oxidative stress and procoagulant activity which may promote atherogenesis.[17] Inflammatory markers do not change when measured the night before and the morning after in children with OSA.[18]

In a group of obese patients with OSA, there was no significant decrease in CRP from baseline to 6 months post adenotonsillectomy. This may have been because of a direct link from the obesity to the inflammatory markers, but also a high proportion of children had residual OSA.[19]

Endothelin 1 has been found to be elevated in some patients with OSA and to decrease post-operatively following adenotonsillectomy. This is a potent vasoconstrictor and may be associated with cardiovascular risk.[20] Tumour necrosis factor (TNF) levels are higher in children with OSA, compared with controls.[21] Myeloid-related protein 8/14, which has an important role in the formation of atherosclerosis, has been found to have higher levels in children with OSA and the levels are in proportion to the severity of the OSA.[22]

Cardiovascular pathophysiology

There is evidence that baroreceptor sensitivity may be impaired in adolescents with sleep-disordered breathing so they do not mount appropriate blood pressure changes to variation in heart rate. In adults this is a risk factor for cardiovascular disease.[23] Blood pressure can be consistently raised in children with sleep-disordered breathing when compared to controls when monitored continuously overnight.[24]

Children with OSA have been shown to have an increased level of urinary catecholamines.[25] The full implication of this is unclear, but it does suggest some cardiovascular effects from OSA. In a large cohort asthma study, children with snoring (based on survey) did not have any abnormal cardiovascular parameters at the age of 8.[26]

Endothelial dysfunction and impaired cognitive abilities appear both to be worsened by worsening OSA, when measured by tests of hyperaemia and neurocognitive tests.[27]

CLINICAL FEATURES/ PRACTICE POINTS

Day- and night-time clinical features

A full sleep history should be taken from children presenting with any adenotonsillar problem and enquired about in patients referred with ear pathology too. The history has two key areas: night-time symptoms and daytime symptoms (**Box 27.1**).

BOX 27.1 Symptoms of OSA

Night-time symptoms	Daytime symptoms
Do they snore? Do they get a good night's sleep or are they restless? Do they wake through the night? Do they struggle with their breathing or stop breathing? This should be explored fully with a clear explanation of respiratory effort with obstruction and respiratory effort with snoring to try to clarify the history. Do they sleep in an unusual position (e.g. extended head)? Do they sweat excessively? Do they wet the bed?	Do they have any behaviour or concentration problems? Do they mouth breathe? Do they struggle with eating? Are they growing normally?

A full ear, nose and throat examination should be undertaken:

- Make a general examination, looking for any craniofacial abnormalities.
- Listen carefully for stertor while awake, or asleep.
- Watch for mouth breathing.
- Carry out an oral examination, to determine the size of the tonsils (**Figure 27.1**). These can be graded by:
  - the Brodsky score[28]
    - 0 - tonsils in fossa
    - 1 - tonsils occupying up to 25% of the airway
    - 2 - 26% to 50%
    - 3 - 51% to 75%
    - 4 - more than 75%
  - the Friedman score[29]
    - 0 - no tonsils
    - 1 - tonsil within pillars
    - 2 - tonsil beyond pillars
    - 3 - tonsil extending ¾ to midline
    - 4 - tonsils touching in midline.

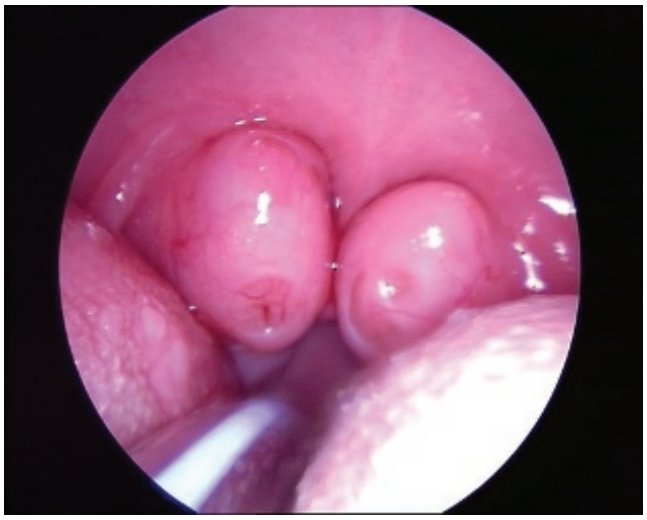

Figure 27.1 Enlarged tonsils in a child about to undergo an adenotonsillectomy for OSA.

- Examine the nose to establish whether there is coexisting rhinitis and whether there is likely to be adenoid hypertrophy.
- Examine the ears for coexisting otitis media with effusion.
- Look for neck lymphadenopathy.

Parents now regularly have access to mobile recording devices and examination of videos on phones or devices can be very helpful in establishing the presence of snoring and obstruction.

A systematic review of the literature has concluded that history is unreliable at predicting OSA.[30] This review was slightly limited as nearly one half of the studies were retrospective, but the others included some well-designed cohort studies. A meta-analysis of the raw data showed history and examination to have poor positive predictive value for obstructive sleep apnoea.

A recent review of the literature and meta-analysis of clinical findings in 10 studies with a total of 1525 patients has looked at the sensitivity and specificity of some of the key clinical aspects of sleep-disordered breathing history.[31] Tonsil size and a history of snoring were the most sensitive clinical findings, but were poorly specific. Conversely, parent reports of apnoeas and daytime somnolence were highly specific but poorly sensitive. It is possible to understand that this is the case. Almost all children with significant OSA will have large tonsils and snore as a sign of their airway obstruction, but not all children with large tonsils will have OSA, and of those who snore, a proportion will be primary snorers. In terms of the apnoeas, if the parents report these, they have a high chance of being significant but, as in reference to sleep physiology, these apnoeas are more likely to occur during REM sleep,[8] which is more prevalent in the latter part of the night when the parents may be sleeping too and may not see these events.

A recent systematic review of tonsil size and the link to obstructive sleep apnoea has found conflicting evidence as to whether tonsil size is predictive.[32] The authors conclude that limitations in the standard sizing system for tonsils, which does not account for overall tonsil volume, may be one of the reasons for this.

OSA is worse during the winter and spring.[33] This may have implications for the time of year that the child is being assessed.

The overall result is that, even in expert hands, a clinical assessment may be inaccurate. Most being assessed will be snorers, so the inaccuracy will lie in differentiating between primary snoring and OSA.

Neurobehavioural symptoms

The neurobehavioural consequences of paediatric obstructive sleep apnoea are now well established in the literature, but new studies continue to clarify the potential deficits.

In a study of 136 children with OSA, ranging from primary snoring to varying degrees of OSA, behaviour and attention were affected in children with both primary snoring and OSA compared to controls, suggesting that primary snoring is not completely benign.[34] Cognitive abilities were also impaired across all groups with sleep-disordered breathing.[35] Memory tasks were impaired in children with all degrees of sleep-disordered breathing too. Interestingly, parents of children with only primary snoring tended to overemphasize their child's memory problems compared to the other groups, possibly as a reflection of behavioural problems.[36]

In a clinical comparison study of 44 snoring children versus 51 non-snoring children derived from a large population survey, polysomnography, neurobehavioural testing and quality of life scores were undertaken. The primary snorers who did not have OSA had significant impairment in language and naming function as well as behaviour.[37] A large cohort of over 1000 German children were studied and those who had primary snoring were found to have hyperactive and inattentive behaviours as well as specifically lower scores in mathematics, science and spelling.[6] All of these changes occur in the absence of hypoxia, and there has been a link to the slow wave activity of the EEG in these children, which may reflect impaired restorative sleep function.[14]

A short-term study of infants showed that those who habitually snored in the first few months of life had significantly decreased cognitive abilities compared to non-snorers at 6 months.[38] This gives rise to the possibility that there is an earlier range of snorers and obstructive patients who are at risk of these deficits. An Australian study demonstrated that both primary snoring children and those with OSA have worse behavioural findings in preschool years, but the cognition was the same as a group of controls. They postulate that this gives a window of opportunity in which treatment can be offered.[39]

A case control study examined the effect of poor sleep hygiene on a group of habitually snoring children versus non-snorers. The poor sleep hygiene did not seem to result in any problem behaviours in the non-snoring group, but in the snoring group there were strong correlations between poor sleep hygiene and behavioural problems.

These included impulsivity, hyperactivity and oppositional behaviours.[40]

Children with OSA have been shown to perform worse in pictorial-based memory tasks when compared to controls.[41]

A cohort of 249 children found that 2-3 years following the birth persistent snoring was associated with higher rates of problem behaviours.[42] Aggressive behaviour at school has been found to have an association with sleep-disordered breathing in a cross-sectional study.[43]

Cardiovascular presenting features

The inflammatory basis of paediatric obstructive sleep apnoea may cast light on the basis of cardiovascular dysfunction in paediatric OSA, which may be subtle and clinically unrecognized in many cases.

An Italian study of 49 children with PSG-proven OSA, compared to 21 matched controls found a higher CRP in the OSA group, and also increased left ventricular mass and early diastolic dysfunction. The dysfunction was worse and the inflammatory markers higher with increasing severity of OSA.[44] This confirms that early aspects of cardiac dysfunction may be higher than appreciated.

Cor pulmonale secondary to pulmonary hypertension is rare, but in a cohort of Taiwanese children, 5 out of 30 had cor pulmonale secondary to OSA. The OSA was more severe in this cohort than the children without cor pulmonale. All children showed improvement in their cardiac status following adenotonsillectomy.[45] This is an unusually high amount of cor pulmonale.

Enuresis

In a population-based study, over 6000 children had questionnaires completed and then polysomnography was undertaken on 597. Nocturnal enuresis was found to be associated with increasing severity of OSA in girls but not in boys.[46]

COMORBIDITY

As discussed above, there are a number of conditions in which OSA has a higher prevalence.

Obesity

Some studies have associated high body mass index (BMI) with OSA.[47] A large population cohort, examining the interaction of obesity, sleep-disordered breathing and cognition, found complex and interdependent relationships between these factors, with each of the factors seeming to have an adverse effect on the others.[48]

A group of 163 overweight children aged 10–16 years underwent polysomnography and neuropsychological testing. Children with worsening OSA were found to have worse concentration, behaviour and academic grades.[49]

Syndromes and associated neuromuscular conditions

Patients with Down syndrome have a high prevalence of OSA.[13] In a radiological study of Down syndrome patients using cervical-spine X-rays which were taken primarily to check on stability of the spine prior to surgery, the lingual tonsils were assessed. A significant increase in the size of the lingual tonsils in the Down syndrome patients compared with control groups was found.[50] Pharyngeal collapse can be found commonly at sleep nasendoscopy of Down syndrome patients.[51]

OSA seems to be particularly prevalent in patients with CHARGE syndrome.[52]

A strong association between craniofacial abnormalities and OSA has been confirmed by a large epidemiological study of over 1000 children.[53]

OSA was found on polysomnography in 95% of a cohort of patients with Treacher Collins syndrome, although the clinical examination was not predictive.[54] As with all cases, a clinical assessment in a subgroup of 13 patients with Treacher Collins syndrome was found not to be reliable for predicting OSA, and the authors suggest use of a polysomnogram in these patients due to the higher prevalence of OSA.[55] The prevalence in this group of children was 54% and the obstruction was multilevel.[56]

Patients with cleft palate may have a higher incidence of OSA, particularly when the palate is closed.[57] In one American study, the prevalence of polysomnographically proven OSA in the cleft palate clinic was 8.5%.[58]

There is a very high rate of polysomnography positive for OSA in patients with syndromic craniosynostosis (see Chapter 19, Craniofacial anomalies). Multiple interventions failed to completely resolve the OSA.[59]

The incidence of OSA in a cohort of 30 French children with achondroplasia was found to be 87%.[60]

Children with Prader-Willi syndrome are at particular risk for OSA and this may worsen with the institution of growth hormone. Adentonsillectomy may decrease but not completely resolve the obstructive sleep apnoea.[61]

The British Thoracic Society guideline identifies that there is a high incidence of sleep-disordered breathing in children with neuromuscular disease.[62]

Interaction of OSA with other conditions

In a group of 131 children with polysomnographically proven OSA, 37 had symptoms of reflux. After 24-hour pH monitoring, 21 were found to have acid reflux. These were treated with a 1–2-month course of proton pump inhibitors and the sleep study was repeated. The reflux group had mean reduction in apnoea–hypopnoea index from 13 to 8. Three children in the mild group had complete resolution of their OSA, while six children with severe OSA had no change in their apnoea–hypopnoea index.[63]

A case control study has demonstrated that children with sickle-cell disease have significantly more upper

aerodigestive tract lymphoid hyperplasia than controls (using MRI) and that the prevalence of OSA in this group of 36 sickle-cell patients (by polysomnography) was 19%.[64] A high incidence (8.3%) of OSA has been noted in patients in Thailand with beta thalassaemia.[65]

An observational study of 108 children with asthma in a children's respiratory clinic found that asthma was worse at 1 year in children who had symptoms of sleep-disordered breathing.[66] In a cohort of 92 poorly controlled asthmatics, 58 were found to have OSA on sleep study, and there were substantial improvements in the asthma following adenotonsillectomy.[67]

An assessment of a clinic population of 84 children with epilepsy found that 44% of severe epileptics and 31% of mild epileptics had symptoms of obstructive sleep apnoea.[68]

BOX 27.2 Indications for paediatric respiratory investigations[69]

- Diagnosis of OSA unclear or inconsistent
- Age <2 years
- Weight <15 kg
- Down syndrome
- Cerebral palsy
- Hypotonia or neuromuscular disorders
- Craniofacial anomalies
- Mucopolysaccharidosis
- Obesity (BMI >2.5 SDS (standard deviation scores) or >99th centile for age and gender)
- Significant comorbidity such as congenital heart disease, chronic lung disease
- Residual symptoms after adenotonsillectomy

INVESTIGATIONS

A UK working party consensus statement on the role of adenotonsillectomy in children with sleep-related breathing disorders said that performing adenotonsillectomy in a child with a history suggestive of OSA and enlarged tonsils, without further investigations, is reasonable and this could be undertaken in a non-specialist unit.[69] If the diagnosis of OSA is unclear or if the child is very young or at the extremes of the weight centiles, then further investigations are indicated. In patients with a suspected underlying syndrome or serious illness, investigations are essential before undertaking further management (Box 27.2).

Diagnostic investigations

OXIMETRY

Overnight pulse oximetry (Figure 27.2) can be useful if more detailed tests of sleep-disordered breathing are not available. It does not require an overnight hospital admission. This investigation provides two pieces of information: heart rate and oxygen saturation. It will detect apnoeas where the oxygen saturations drop, usually with an accompanying rise in heart rate. An oximetry scoring system has been defined by a group from Canada, which was associated with increasing severity of OSA in a prospective cohort study.[70] Oximetry has a high positive predictive value (97%) but, because not

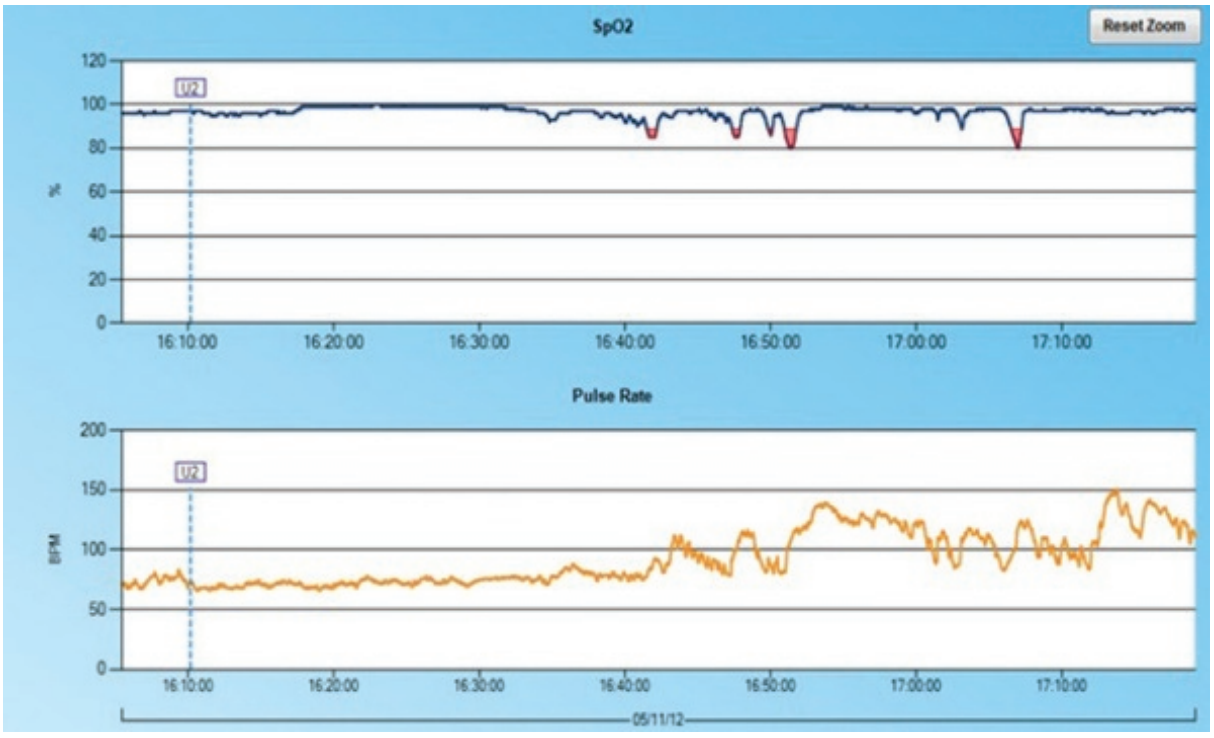

Figure 27.2 An oximetry trace showing periods of desaturation in red (SpO_2) with a rise in heart rate. With a positive history and examination, this has a high positive predictive value for OSA.

all apnoeas result in a drop in saturations, the negative predictive value is low (53%).[71]

POLYSOMNOGRAPHY

Polysomnography (PSG, a sleep study, **Figure 27.3**) is currently the gold standard of investigation. In this investigation, the child is monitored during sleep, usually in the hospital. This can be a variable quantity of measurements depending on local resources. The minimum features should be measurements of oxygen saturation, airflow, respiratory effort, electrocardiograph, video and sound.[13] This investigation can measure apnoeas (cessation in airflow) or hypopnoeas (reduction in airflow). These two are often combined as the apnoea–hypopnoea index (AHI) which is the total number of apnoeas and hypopnoeas per hour of sleep.

A study looking at visual scoring of arousals versus the interpretation of EEG found that the visual scoring of arousals was more appropriate than relying on the EEG alone.[72] A large case control study looked at the differences in sleep architecture on polysomnography for children of preschool versus school age and found some significant differences. Children of pre-school age were more likely to have central apnoeas, but less likely to awaken than older children with comparable levels of sleep-disordered breathing. This has implications for the interpretation of sleep studies for the different age groups.[73] Spruyt et al.[74] have demonstrated that children who have overnight polysomnography can be divided into six groups with clusters of severity based on polysomnographic criteria.

There is some questionnaire evidence that sleep patterns of children differ when in hospital having a sleep study, particularly in the under 3s group.[75] This indicates that caution needs to be applied to the interpretation of these tests and may be best assessed in the context of the parent's description of whether this was a typical night's sleep.

The way hypopnoeas are scored can make a large difference to the AHI. In a study looking at the American Academy of Sleep Medicine definition versus the Stanford definition (which requires no drop in oxygen saturation), the amount of OSA diagnosed varied from 19% to 99%.[76]

OTHER INVESTIGATIONS

- An ambulatory device (ApneaLink Plus, ResMed, Poway, Ca, USA) measuring nasal airflow, chest movement and oxygen saturation has compared favourably with polysomnography in the detection of obstructive sleep apnoea in a group of obese adolescent patients.[77]
- Actigraphy, using a wrist-worn sensor to detect sleep and wakefulness via motor activity, has been shown to be a good approximation to polysomnography in terms of sleep-wake pattern, but it gives no other information.[78,79]

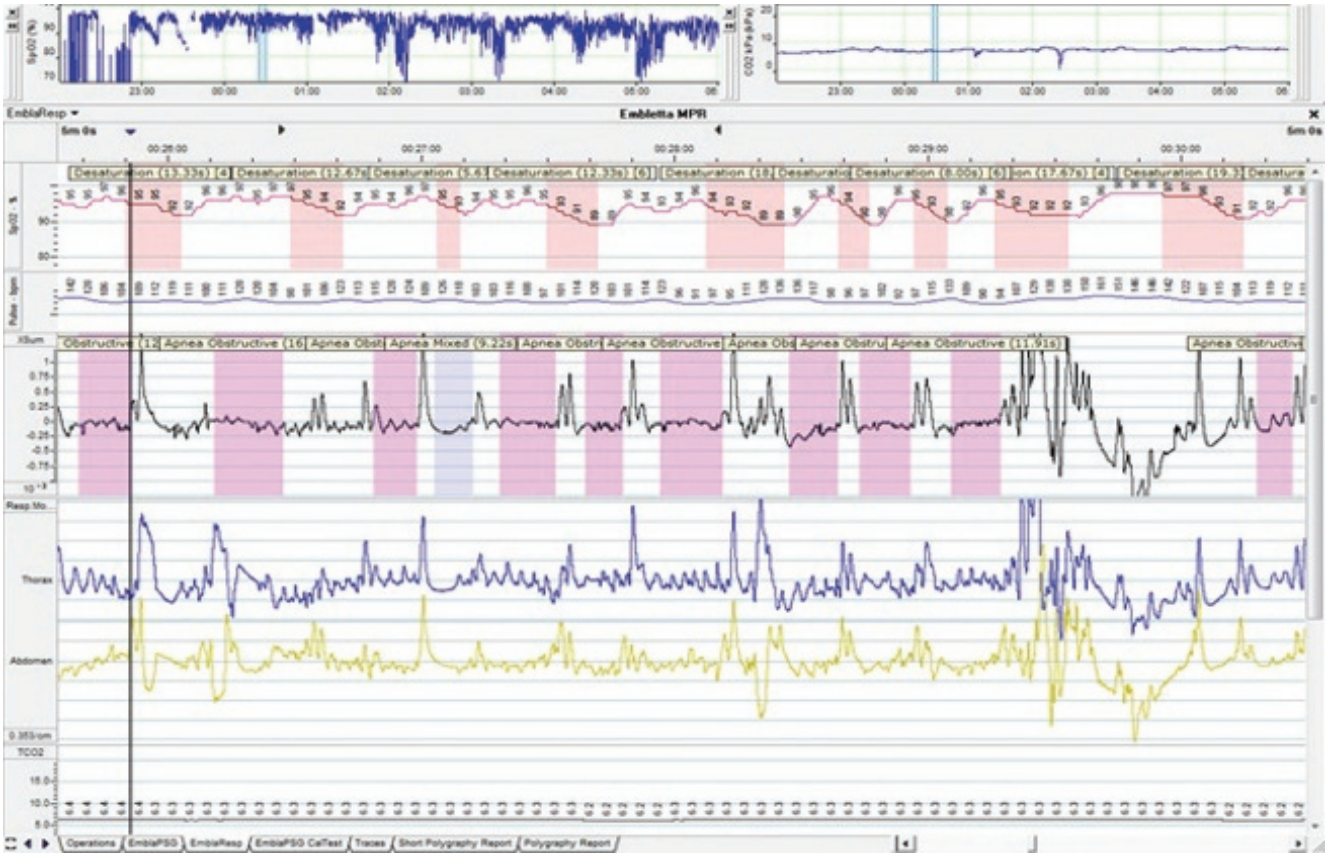

Figure 27.3 Part of a polysomnography study demonstrating desaturations (low SpO_2) and decreased airflow despite respiratory effort, confirming OSA.

- Cardiopulmonary coupling, using devices which measure the synchrony between pulse and respiration, has been proposed as a measure of sleep quality. In a study of OSA patients before and after adenotonsillectomy, the cardiopulmonary coupling appears to show improvement in sleep parameters for quality of sleep before the EEG.[80]
- Oesophageal pressure monitoring at the time of polysomnography to measure changes in intrathoracic pressure has been found to be more predictive for certain neurobehavioural variables.[81]
- Pulse transit time has shown some correlation with OSA at AHI above 3, but it is more limited at picking up milder OSA and differentiating between primary snoring.[82]
- Complementary investigations to measures of attention, such as the event-related potential, measured electrophysiologically, have shown some promise as measures.[83]
- Dynamic MRI is at an experimental stage, but has been used to demonstrate flow changes in paediatric patients with OSA.[84]
- Respiratory inductance plethysmography bands have shown promise in conjunction with oximetry as a pre-polysomnogram screening investigation.[85]
- Infrared monitoring of movements and chest/abdominal asynchrony during obstruction has also been proposed as a method of diagnosis.[86]

CARDIAC INVESTIGATIONS

If there are concerns about the severity of OSA, cardiac investigations in the form of ECG and echocardiography can be undertaken, but routine use of echocardiography has not been shown to be productive in the assessment of patients with OSA.[87]

TREATMENT

Diet and exercise

With the increasing proportion of obese patients, issues of body mass index and the underlying causes should be addressed.

A longitudinal study from Belgium looked at the impact of diet and exercise in a group of children with obesity and OSA. Of 114 obese patients, 41 had sleep apnoea. After weight reduction, 29 of the 41 patients had resolution of the OSA. Those who did not get resolution with weight loss were significantly more likely to have tonsil hypertrophy. Uric acid (a measure of oxidative stress) and CRP were significantly reduced by treatment.[88]

Medicines

A study in Brazil has looked at nasal douching and topical nasal steroids used in a sequential manner to treat adenoid hypertrophy. The study showed no change in the endoscopic appearance of the adenoids after douching alone, but a reduction after topical steroids for 40 days. The results of this are very restricted due to the lack of randomization and blinding.[89]

The Cochrane review has found in a short-term study that topical nasal steroid had a positive effect on the AHI of children with mild to moderate OSA.[90] There has been a well-produced double-blind randomized control trial of nasal steroids (6 weeks fluticasone) which has shown a reduction in the AHI.[91]

There is some evidence that treatment of reflux can help reduce the AHI in mild cases.[63]

Surgery

ADENOTONSILLECTOMY

Trials

The existing literature in this area demonstrates clearly the lack of level 1 evidence to inform treatment decisions. The 2015 Cochrane systematic review 'Tonsillectomy or adenotonsillectomy versus non-surgical management for obstructive sleep-disordered breathing in children' found only three trials meeting the criteria.[92]

The largest of these is the Childhood Adenotonsillectomy Trial (CHAT) from the USA, with 464 children randomized to early adenotonsillectomy or watchful waiting. The age inclusion criteria were 5–9 years and children who had polysomnographically proven OSA. The primary outcome measure was neuropsychological testing and there was no difference between the treatment and control arms, but secondary outcome measures of quality of life (paediatric sleep questionnaire, OSA-18, modified Epworth – all three of which are disease-specific – and pedsQL – measuring general quality of life) did show a significant difference. The control arm showed a spontaneous resolution rate of physiological sleep study measurements in 46% of the control arm versus 79% of the treatment arm. This was a negative trial for the primary outcome, and the high rate of resolution of symptoms in the control arm supports the clinical observations of spontaneous resolution beyond the age of 5 years due to reduction in the volume of adenotonsillar tissue.[93, 94]

In the second-largest study 80 patients with Down syndrome or muccopolysaccharidosis and polysomnographically proven OSA were randomized to adenotonsillectomy or CPAP. These comorbidities often result in more severe OSA and are therefore excluded from many larger studies.[95]

The final study was a small trial with just 29 patients with negative sleep studies and clinical symptoms randomized to adenotonsillectomy or watchful waiting and just 20 analyzed. This was judged to be a very poor quality study due to the dropout rate and the small initial sample size.[96]

There are several current trials comparing adenotonsillectomy versus watchful waiting in varying severities of sleep-disordered breathing from snoring to obstructive sleep apnoea. These include the Preschool Obstructive Sleep Apnoea Tonsillectomy Adenoidectomy (POSTA) trials from Australia, looking at younger age groups than the CHAT study.

A previous Cochrane review of treatment of obstructive apnoea by adenotonsillectomy only found one paper meeting the Cochrane criteria,[97] and this was primarily concerned with surgical technique.[98] Patients were randomized to either radiofrequency tonsil reduction and adenoidectomy or conventional adenotonsillectomy. There were no differences in the outcome measures.

An RCT looked at the addition of pharyngeal pillar closure to standard adenotonsillectomy. Patients with OSA were randomized to receive either a standard cold steel dissection adenotonsillectomy or the same procedure followed by apposition and closure of the pharyngeal pillars. Despite being adequately powered, there was a high dropout rate and a small length of follow-up. There was improvement in quality of life (QOL) scores and AHI for both techniques but no significant difference between them. In light of the limitations of the study these results should be treated with caution.[99]

Longitudinal studies

The main physiological outcome is the AHI from polysomnography as described above. There are a number of studies which demonstrate a reduction in the AHI and these have been summarized in a meta-analysis.[100] Included in this were paediatric patients with no underlying syndrome or diagnosis who underwent adenotonsillectomy with pre- and post-operative polysomnography. The meta-analysis pooled data on 355 children from 14 series. The data are limited by the fact that this is from case series and there are no control groups. An improvement of polysomnography to normal occurred in 83% and a reduction in the AHI of 14 events per hour was found.

More recently there has been a large multicentre retrospective analysis of outcomes of adenotonsillectomy at centres across North America. This analysis included 578 children and the AHI fell significantly from 18.2 pre-operatively to 4.1 post-operatively. However, only 27% of patients had a normal AHI of less than 1. Severe OSA pre-operatively and obesity were predictive of residual OSA post-operatively.[101]

A small study looked at outcomes of adenotonsillectomy in a group of patients with craniosynostosis and upper airway obstruction with moderate to severe OSA. Three out of five patients avoided a tracheostomy, and one of five patients had complete resolution of their symptoms.[102]

A study of 101 children with OSA, who underwent adenotonsillectomy, found that there was a significant reduction in central apnoeas, in those who experienced them, following the procedure.[103]

Adenotonsillectomy was an effective treatment for OSA in a cohort of cleft palate patients, with a reduction of mean AHI from 17.6 to 1.9.[57]

Use of a nasopharyngeal airway has been found to be a useful adjunct to surgery and seems to decrease reliance on PICU.[104]

Tonsillectomy technique

There is increasing evidence that intracapsular tonsil techniques may confer some advantages over conventional techniques. In a series of 500 patients who underwent Coblation® intracapsular tonsillectomy and adenoidectomy, the bleed rate was 0.4%. Requirements for analgesia were low and parental satisfaction and quality of life were high.[105] A study of quality of life by proxy at 3 months and 2 years found no difference between subtotal and full adenotonsillectomy.[106]

JAW DISTRACTION

Bilateral distraction osteoneogenesis has proven to be a reliable technique in producing an adequate pharyngeal airway in children with micrognathia and subsequent pharyngeal restriction secondary to tongue base collapse. In a report from Israel all 11 patients with tracheostomies were subsequently decannulated following jaw distraction with near normal oximetry.[107]

Rapid maxillary expansion has been proposed as an alternative technique in children with retrognathia. In a group of 15 children, 8 had a better respiratory distress index following treatment but 7 were either unchanged or worse.[108] For more detail, see Chapter 19, Craniofacial surgery.

TONGUE REDUCTION

In Beckwith–Wiedemann syndrome and other selected syndromes with macroglossia, tongue reduction may be indicated and results are usually good.[109]

Continuous positive airway pressure

Continuous positive airway pressure (CPAP) may be required in children where treatment is not possible, where treatment is awaited, or where treatment has failed. It is usually used in cases of moderate to severe OSA.

Adherence to CPAP can be poor, particularly in older children. In a sample of 51 patients the mean amount of time spent with CPAP on was just 3.3 hours per night. The authors developed a questionnaire to identify barriers to adherence.[110] A randomized controlled trial of different methods of administering CPAP showed no improvement in compliance with different delivery systems.[111] One American study linked socioeconomic factors rather than disease severity to poor compliance.[112]

CPAP is often reserved for treatment failures, complicated cases with comorbidities and in obesity. The first study to look at neurobehavioural outcomes in 52 patients on CPAP alone examined a heterogeneous group of patients. Assessments were performed at baseline and after 3 months of treatment. There were significant improvements in both disease-specific and general quality of life (QOL) scores. These improvements occurred with a mean use of just 3 hours per night.[113]

The only randomized controlled trial concerning positive airway pressure in paediatric OSA looked at the use of continuous or bilevel CPAP in children who were

unsuitable for adenotonsillectomy and found no difference between the methods.[114]

Nasopharyngeal airway

Nasopharyngeal airways can be used for the long-term management of patients with craniosynostosis and can result in significant improvements in quality of life (QOL) scores.[115]

Analgesia post-adenotonsillectomy for OSA

Paracetamol is considered part of the standard regimen for analgesia post-adenotonsillectomy. Non-steroidal anti-inflammatory medications are widely used in the UK, but there are concerns about a potential bleeding risk associated with their use. A recent Cochrane review with over 1000 children looking at post-operative bleeding in adenotonsillectomy with NSAIDs has shown no statistically significant increase in bleeding, but greater numbers would be needed to prove conclusively there was no increase.[116]

Opioid analgesics need to be managed very carefully. In 2012 the FDA in the US reported three deaths and one severe respiratory depression in children who had undergone tonsillectomy or adenotonsillectomy for obstructive sleep apnoea and had received codeine. It appeared that the children were 'ultra-rapid metabolizers' with a genetic variant which made the liver enzyme p4502D6 much more active. It is thought that this gene variant can exist in up to 7% of the standard population in the US, but up to 29% of those of Ethiopian origin. These children rapidly metabolize a standard dose of codeine, resulting in high serum levels of morphine.[117, 118]

The UK government has restricted the use of codeine in children, particularly those undergoing adenotonsillectomy. The relevant advice is shown in **Box 27.3**.[119]

A randomized double-blind study compared post-operative morphine with dexmedetomidine, a sedative medicine. The dexmedetomidine produced less respiratory compromise as measured by end tidal CO_2, but pain scores were higher.[120]

Location of post-operative care

While the majority of patients with OSA can be managed safely in a standard children's ward environment, careful consideration must be given to whether those at higher risk of respiratory compromise post-operatively need more specialized support (see below). In a prospective study looking at respiratory complications following adenotonsillectomy for OSAS the rate was found to be 10.4%. However, in children with no comorbidity, only 1.2% of these had a problem beyond 6 hours. This is suggested as a basis for day-case tonsillectomy in children without comorbidity. The rate of complications in those with comorbidity at 6 hours post-surgery was 21.6%.[121]

BOX 27.3 UK Government relevant advice on codeine use[119]

Codeine should only be used to relieve acute moderate pain in children older than 12 years and only if it cannot be relieved by other painkillers such as paracetamol or ibuprofen.

Codeine is contraindicated in all children (i.e. younger than 18 years) who undergo tonsillectomy or adenoidectomy (or both) for obstructive sleep apnoea.

Codeine is not recommended for use in children whose breathing might be compromised, including those with: neuromuscular disorders; severe cardiac or respiratory conditions; upper respiratory or lung infections; multiple trauma; or extensive surgical procedures. The symptoms of morphine toxicity may be increased in these settings.

In children aged 12–18 years, the maximum daily dose should not exceed 240 mg. This may be taken in divided doses, up to four times a day at intervals of no less than 6 hours. It should be used at the lowest effective dose for the shortest period. Duration of treatment should be limited to 3 days and, if no effective pain relief is achieved, treatment should be reviewed by a physician.

Information should be given to parents and caregivers on how to recognize the signs of morphine toxicity, and advice should be given to stop giving the child codeine and to seek medical attention immediately if their child is showing these signs or symptoms.

Symptoms of codeine toxicity include: reduced levels of consciousness; lack of appetite; somnolence; constipation; respiratory depression; 'pinpoint' pupils; nausea and vomiting.

Codeine is contraindicated in all patients of any age known to be CYP2D6 ultra-rapid metabolizers.

Post-operative complications

The main risk of adenotonsillectomy is post-operative haemorrhage, which has a rate of approximately 4%. A randomized allocation study of 50 children, allocated to either dissection adenotonsillectomy or Coblation® for obstructive sleep apnoea, found less time and less intra-operative blood loss with Coblation®. The failure to find a difference in secondary haemorrhage is not surprising given that this study is vastly underpowered to detect post-operative complications.[122]

A large case controlled trial undertaken in the US looked at over 9000 tonsillectomies, with an overall bleed rate of 2.4%. Using logistic regression, the bleed rate in tonsillectomies was found to be half the rate in those done for recurrent acute tonsillitis.[123]

Children who have OSA are at increased risk of peri-operative respiratory complications. They may be more sensitive to opiates and inhalational anaesthetic agents and are at risk of pulmonary oedema. In children who have been identified as high risk, surgery should be performed in a hospital with paediatric intensive care facilities.[124] In cases at high risk of airway compromise, a nasopharyngeal airway can help reduce the reliance on PICU.[125]

A retrospective review of 993 patients aged 3 years and under found a 9.9% complication rate, with airway obstruction, desaturations and bleeding being the three commonest complications.[126] Younger age (less than 2 years), nasal obstruction and cardiovascular

comorbidities were predictors of airway complications in this group.

Another retrospective review showed that young age, high apnoea–hypopnoea index and intra-operative laryngospasm were linked with complications.[127]

A systematic review has demonstrated that children with OSA put on a significant amount of weight post-operatively and this can predispose some to obesity.[128]

Treatment failure

Residual OSAS following adenotonsillectomy has been reported in 11.6% of children in one study following polysomnography.[129] It has been reported as high as 31% of children in some studies, with higher proportions in children with severe OSA, following surgery.[130] Hypertrophy of residual lymphoid tissue in Waldeyer's ring such as the lingual tonsillar tissue may be responsible for some failures.[131, 132]

Sleep nasendoscopy has been suggested as a method to assess the site of obstruction in airway failures. In a group of 13 children this was seen to be a combination of adenoid regrowth, inferior turbinate hypertrophy and tongue base collapse.[133] There may also be coexistent airway pathology. In a group of 43 patients with OSA secondary to laryngomalacia, 32 had already undergone adenotonsillectomy without resolution of symptoms. Sleep nasendoscopy was an effective way of diagnosing the condition and treatment with supraglottoplasty resulted in a statistically significant reduction in the AHI.[134]

Synchronous airway lesions were found in nearly two-thirds of patients in one series who were less than 3 years of age and undergoing adenotonsillectomy, but only a small number may require surgical intervention. Laryngomalacia and subglottic stenosis were the commonest pathologies.[135]

In a study looking at either supraglottoplasty or lingual tonsillectomy following adenotonsillectomy when there was residual OSA, there was improvement following these procedures, but less for lingual tonsillectomy in obese patients, and less improvement from supraglottoplasty in patients with other comorbidities.[136]

A retrospective analysis of 31 patients who had refractory obstructive sleep apnoea, who were subsequently treated with geniohyoid advancement, radiofrequency tongue base reduction and lingual tonsillectomy, resulted in a success rate of 61% judged by polysomnography.[137]

QUALITY-OF-LIFE OUTCOMES IN SLEEP-DISORDERED BREATHING

Measuring outcomes other than the physiological sleep outcomes is of increasing interest. Areas include neurocognitive outcomes and also quality of life by proxy. The first UK study to measure quality of life improvement was by Georgalas.[138] In a cohort of patients, adenotonsillectomy improved all domains of the Child Health Questionnaire. There has been further work on the use of disease-specific instruments in the UK.[139] In North America there is widespread use of disease-specific quality of life measures such as the OSA-18.[140] A review article found 11 publications measuring changes in behaviour, neurocognition and quality of life following adenotonsillectomy.[141] The authors probably overrate the quality of evidence as these studies are generally prospective single-sample observational studies, although 5 of the 11 do include a control group. Universal improvement in quality of life is reported in these studies. Behaviour and neurocognitive measures also show improvement. One year following adenotonsillar surgery in a group of preschool children, the OSA group showed fewer behavioural problems and a significant improvement in behaviour and quality of life.[142] Longer-term studies demonstrate that the quality of life improvement can be sustained over up to 4 years.[143, 144]

Quality of life studies generally fall into two categories: cross-sectional studies, which are looking at quality of life for a specific condition, and longitudinal studies, which look at the change in quality of life following an intervention.

Cross-sectional studies

Two of these studies were used to develop two of the main disease-specific quality of life tools: the OSA-18 and the Tonsil and Adenoid Health Status Instrument.[145, 146] The main differences between them are that the Tonsil and Adenoid Health Status Instrument was designed for any adenotonsillar disease, and children did not have polysomnographic investigation. The OSA-18 was designed specifically for sleep-disordered breathing and an abbreviated form of polysomnography was performed. The Tonsil and Adenoid Health Status Instrument has been used to derive the T14 instrument for UK practice. This instrument captures information in domains about the obstructive and infective symptoms which affect children, and the subsequent impact on quality of life through issues such as contact with medical services and time off school.

Three other studies looked at general quality of life measures in sleep-disordered breathing, and all found a negative impact of sleep-disordered breathing on quality of life.[147–149]

Two studies investigated obesity and sleep-disordered breathing using a general quality of life measure and found sleep-disordered breathing in obesity to impair quality of life.[150, 151]

Longitudinal studies

The OSA-18 had its development completed in one of these longitudinal trials.[140] It has been used to demonstrate large changes following adenotonsillectomy in the disease-specific quality of life for a general group of patients,[144, 152–159] and specific subgroups of severe OSA[160] and obesity.[161] The OSA-18 has also been used to demonstrate improvement in disease-specific quality of life in children with cerebral palsy[162] and attention deficit hyperactivity disorder (ADHD).[163]

One of the studies used a non-validated questionnaire so is difficult to compare to the others.[164]

The OSD-6 (obstructive sleep disorders 6) was developed in one of the studies[165] and subsequently used in longitudinal studies which show changes in all domains following adenotonsillectomy including improvements up to 3 years after intervention.[166, 167]

The Tonsil and Adenoid Health Status Instrument was used to evaluate the changes following adenotonsillectomy. This showed significant improvement across most scales in a longitudinal study.[168]

Most of the studies have the same limitations in that they feature usually consecutive or convenience samples of children and there is mostly one group. There is potential for bias in the inclusion criteria in a number of the studies. The intervention is made and there is a longitudinal design to the studies. While they all show improvement across the specified domains, there are no control groups in the studies who do not undergo the procedure, so it is not possible to state conclusively that the change is due to the intervention alone, or what magnitude of change there would be compared to a control group.

The only randomized controlled trial concerning quality of life was an evaluation of microdebrider tonsillotomy versus electrocautery to perform adenotonsillectomy. The microdebrider group were more likely to get back to normal activities and diet quicker than the electrocautery group.[169]

MANAGEMENT ALGORITHMS

For the purposes of discussion for this chapter, the term 'specialist children's hospital' refers in the UK to a hospital with specialist paediatric ENT surgeons, anaesthetists and intensive care facilities. The term 'non-specialist centre' refers in the UK to a unit without paediatric intensive care or specialist paediatric ENT or anaesthetic provision. Box 27.4 lists circumstances in which a child should be referred for treatment to a specialist children's hospital.

BOX 27.4 Children who should be referred for treatment in a specialist children's hospital[69, 124]

Age <2 years
Weight <15 kg
Failure to thrive (weight <5th centile for age)
Obesity (BMI >2.5 SDS or >99th centile for age and gender)
Severe cerebral palsy
Hypotonia or neuromuscular disorders (moderately severely or severely affected)
Significant craniofacial anomalies
Mucopolysaccharidosis and syndromes associated with difficult airway
Significant comorbidity (e.g. congenital heart disease, chronic lung disease. ASA 3 or above)
ECG or echocardiographic abnormalities
Severe OSA (described by polysomnographic indices including obstructive index >10, respiratory disturbance index (RDI) >40, and oxygen saturation nadir <80%)

Based on the evidence presented in this chapter the following management algorithm is suggested.

Non-specialist centre

A careful history and examination should be taken. Using the UK guidelines there are factors which can be derived from the history and factors which can be measured that would guide whether it is appropriate to treat in a non-specialist environment (without PICU support) (see Box 27.3).[69]

The factors derivable from the history are:

- age
- severe comorbidity which could influence the anaesthetic and post-operative course (heart/lung)
- comorbidity with impact on pathophysiology of OSA (cerebral palsy, hypotonia/neuromuscular conditions, craniofacial abnormalities, mucopolysaccharidoses or other airway syndromes).

Age 2 years or less would seem to be a sensible point at which a child should have an anaesthetic for adenotonsillectomy to treat obstructive sleep apnoea in a specialized children's hospital or a hospital with high-level children's facilities. The heart and lung factors make it more likely that a child could have intra- or post-operative difficulties therefore would be best managed in a centre with specialist paediatric anaesthetists and paediatric intensive care facilities. The comorbidity with an impact on pathophysiology are conditions which make it more likely that OSA will be more severe and more likely to have incomplete resolution following tonsillectomy and adenoidectomy alone. Removal of small amounts of tissue to try to make partial improvements in patients with OSA can also result in worsening of the condition if there is post-operative swelling.

Consideration should be given to referring these children to specialist children's hospitals prior to any investigations as it is likely that full polysomnography rather than pulse oximetry would be undertaken.

Factors which can be measured are:

- weight
- ECG – to look for cardiac complications
- oximetry – to exclude moderate to severe OSA.

In children over 2 years who have no comorbidity as listed earlier, it is sensible to undertake the above investigations. This is to ensure that children are not at the extremes of weight, do not have cardiac complications and do not have moderate to severe OSA. As discussed in 'Oximetry' above, the investigation has a high positive predictive value but a low negative predictive value.[71] Thus an oximetry trace showing clusters of desaturation is likely to represent moderate to severe OSA. A 'normal' oximetry trace may represent mild OSA/sleep-disordered breathing.

A child with minimal desaturations, none of the above comorbidity and not at the extremes of weight or age can

safely be managed in a non-specialist hospital environment. If the oximetry trace shows no desaturation in the presence of positive features of apnoea on history and large tonsils, the patient is likely to have obstructive sleep apnoea but may have primary snoring alone. Treatment with adenotonsillectomy in these circumstances will result in treatment for most patients with OSA, but may also result in treating primary snorers. There is increasing evidence that primary snoring is not a benign condition and may have neurobehavioural consequences, but there is no research or established role at this stage for adenotonsillectomy in the treatment of primary snoring.[34]

The other option in these circumstances is to refer the child to the local paediatric sleep team for a polysomnogram, which would give diagnostic clarity about the presence/absence of OSA.

Specialist children's hospital

A similar list of conditions exists in the UK guidelines for which children require investigations prior to treatment of OSA.[69]

In the specialist paediatric hospital setting the decision-making process will usually depend on establishing the need to investigate prior to intervention or proceed directly.

As with the non-specialist hospital assessment of the age, cardiorespiratory comorbidity and comorbidity causing or impacting on the severity of OSA can be derived from the clinical findings. Weight and ECG can be measured.

In many centres, in children with no significant comorbidity with clinical findings suggestive of OSA, the decision is taken to proceed directly to adenotonsillectomy. This should be an informed discussion with the parents explaining that, while there is a probability that a child with obstructive features in the history and large adenotonsillar tissue does have obstructive sleep apnoea, there is a chance that they may have primary snoring only.[31] Some parents and surgeons will prefer to investigate for improved diagnostic accuracy, and this can be in the form of oximetry or polysomnography.

If polysomnography is negative, the family can be reassured. If it shows evidence of OSA, treatment should be discussed. If it is mild, consideration could be given to intranasal steroids if the family are keen to avoid surgery.[91] If it is moderate or severe, consideration should be given to adenotonsillectomy.

If a child is at the extremes of weight, has serious cardiorespiratory comorbidity, craniofacial, muscle tone or syndromic problems, a polysomnogram should be performed prior to any intervention. This allows an improved diagnostic certainty in patients who are at higher risk for respiratory complications and also risk stratification. Surgery can be avoided in those who do not have OSA, while those who have moderate to severe OSA can have appropriate arrangements made for post-operative care. This will vary between centres from prolonged recovery, use of airway adjuncts to high dependency or intensive care beds. The intervention clearly needs to be tailored to the individual condition, and in those with syndromic or craniofacial problems it should be a multidisciplinary team decision.

CONCLUSION

Paediatric OSA is a common condition which will be seen by the majority of ENT surgeons. It is important to understand the pathophysiology, and to appreciate the limitations of history and examination in the diagnosis. Investigations need to be considered carefully in the context of their predictive values and a suggested algorithm for hospitals with and without paediatric anaesthesia and intensive care is suggested. Intervention in this condition can result in large and sustained quality of life, but a good awareness of the comorbidities which could result in complications or a poorer outcome is essential.

FUTURE RESEARCH

- Improved abbreviated diagnostic testing.
- Good randomized evidence to support decision-making.
- Increasing use of intracapsular tonsillectomy.
- Better understanding of the inflammatory basis of OSA.

KEY POINTS

- Paediatric obstructive sleep apnoea (OSA) is common, with an incidence of up to 2%.
- Clinical features in the history and examination can be unreliable in predicting OSA.
- Oximetry has a high positive predictive value but a low negative predictive value.
- There is good longitudinal evidence of physiological and quality of life improvement with adenotonsillectomy, but there has been only one completed large-scale randomized controlled trial.

CHAPTER
28

STRIDOR

Kate Stephenson and David Albert

SEARCH STRATEGY

The senior author has a personal bibliography of key papers on paediatric airway obstruction. This was supplemented with a Medline search using the following keywords: stridor, child, neonatal, paediatric, laryngomalacia, tracheomalacia, vocal cord palsy, vocal fold palsy, vascular ring, stenosis, laryngotracheobronchitis, croup, tracheitis and airway obstruction.

The rationale for most interventions in childhood stridor is based on the practices of experienced clinicians. Few treatments have been subjected to controlled trials. Hence, apart from steroid and nebulized adrenaline therapy in croup, recommendations in this chapter are Grade C and D.

INTRODUCTION

This chapter discusses the evaluation and management principles of a child with stridor. It then reviews the usefulness of special investigations. The clinician is directed to the appropriate chapter for detailed information on specific conditions. Care of the acutely stridulous child is also described.

The challenge of managing a stridulous child

A child labelled with a 'diagnosis' of stridor may have significant underlying pathology. Stridor is a symptom and not a diagnosis. History and general examination alone are insufficient for a firm conclusion to be drawn. Deciding which patients to investigate is sometimes difficult. Even after non-invasive investigations such as imaging there may remain a number of differential diagnoses. Awake flexible endoscopy is very useful but gives little or no information beyond the level of the glottis.

The definitive diagnostic technique of laryngotracheobronchoscopy (LTB) requires an experienced team of surgeon, anaesthetist and nursing staff. Both the equipment and expertise required are highly specialized and are not available in all institutions. Transfer of the child with stridor may be necessary and should be carefully managed.

A child with stridor typically induces significant anxiety in the carer and should be a clinical priority for the medical professional. In the acute situation the paediatric airway can deteriorate rapidly. In a specialized unit this is rarely a problem, with experienced anaesthetists to intubate and surgeons to perform the rare emergency tracheostomy. In a paediatric ward, emergency room or non-hospital setting, rapid deterioration can prove a real challenge.

Anatomical and physiological considerations

Neonates and young children develop upper airway obstruction and respiratory failure more readily than older children and adults. A significant contributor to this increased risk is the structure of the airway in the younger child. Mucosal swelling is more likely to result in a comparatively greater degree of obstruction of the smaller upper airway.

AIRWAY DYNAMICS

Poiseuille's law (the Hagen–Poiseuille equation) may be applied to the airway and dictates that the airway resistance is inversely proportional to the fourth power of its radius; a 50% reduction in the radius of the airway therefore results in a 16-fold increase in resistance to airflow. One millimetre of narrowing in a 4 mm diameter infantile airway thus results in a 75% change in airflow. As cross-sectional

area decreases, airflow velocity increases. The smaller the airway, the greater the impact of airway oedema and the more grave the concern.

The Bernoulli principle is also of fundamental importance in relation to the paediatric airway. Increased airflow velocity results in negative pressure on the walls of the airway leading to inward collapse. Previously smooth or 'laminar' airflow then becomes more turbulent. The 'Reynolds number' is a quantity described in fluid mechanics that defines the point at which the transition between laminar and turbulent flow occurs. Factors in the equation are the density, viscosity and velocity of the 'fluid', and the diameter of the 'pipe'. Increased turbulence is highly important, greatly increasing airway resistance. Increased airway collapse occurs with vibration of closely apposed tissues and the resultant noise of stridor.

Definitions and characteristics of stridor

Noise originating in the larynx or trachea is typically high-pitched and termed 'stridor'. It may have a musical quality. In contrast, the low-pitched snoring type of noise made by naso- and oropharyngeal obstruction (and rarely by the supraglottic larynx) has a rougher quality and is best described as 'stertor'. Obstruction of the small intrathoracic airways, such as in asthma, is termed 'wheezing'. A rigid differentiation between stridor and stertor cannot always be made and too rigid a distinction can lead to incorrect diagnosis (Figure 28.1).

	Airway noise	Voice/cry	Cough
Naso-/oro-pharynx	Stertor	Muffled	Typically absent
Supraglottis/glottis	Stridor-inspiratory	Hoarse (glottis)	Barking
Subglottis/upper trachea	Stridor-biphasic	Unchanged	Brassy
Lower trachea	Stridor-exspiratory	Unchanged	Wet sounding

Figure 28.1 Clinical presentation according to level of upper airway obstruction.

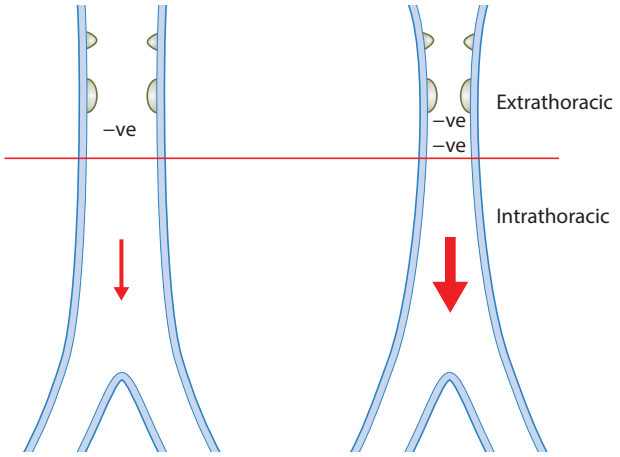

Figure 28.2 Increasing collapse on inspiration with extrathoracic obstruction.

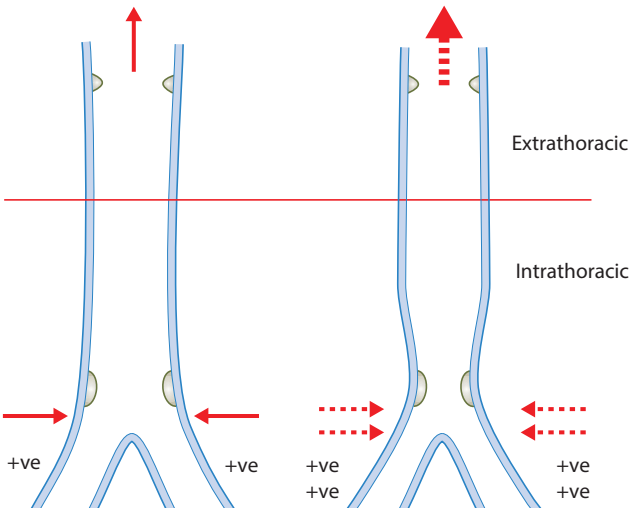

Figure 28.3 Increasing collapse on expiration with intrathoracic obstruction.

Typically, inspiratory stridor is due to an extrathoracic obstruction (Figure 28.2) from the larynx or high trachea. Bronchial or low tracheal obstruction produces an expiratory stridor. Biphasic stridor can occur with obstruction anywhere in the tracheobronchial tree. Even if expiratory stridor is absent, a prolonged expiratory phase may be present, indicating an intrathoracic obstruction (Figure 28.3).

EVALUATION OF THE CHILD WITH STRIDOR

The aim of the history, examination and special investigations is to determine not only the site and cause of the obstruction (the diagnosis) but also its effect on

the airway (the severity). It is important to consider the effect of airway obstruction on feeding, sleep, exercise and growth.

History

PERINATAL HISTORY

The obstetric and perinatal history is often relevant. This is particularly true if the child was born prematurely and required ventilation. Neonates admitted even for short periods to intensive care or a special care baby unit (SCBU) may have had endotracheal intubation but the parents may not volunteer this important information. Beware the term 'intubation', as this may be taken to mean the passage of a nasogastric tube or even suction of oronasal secretions. A history of a difficult delivery is also linked to vocal cord palsy.

Stridor that is present at birth, i.e. with the child's first breath, is unusual. This generally denotes a significant fixed congenital narrowing such as a laryngeal web, subglottic or tracheal stenosis or bilateral vocal cord palsy. Other dynamic conditions such as laryngomalacia typically become evident in the first few weeks of life. A gradual increase in severity of airway compromise implies progression of an obstruction which may be intrinsic (luminal), as in the case of a subglottic haemangioma, or extrinsic, as with a mediastinal mass.

TABLE 28.1 Symptoms associated with varying causes of airway obstruction

Symptoms	Typical diagnoses	
Prolonged expiratory phase	Tracheal and bronchial obstruction (e.g. tracheobronchomalacia, stenosis)	
Cough	TOF Vocal cord palsy Cleft larynx Foreign body Tracheomalacia Reflux	
Aspiration	TOF Vocal cord palsy Cleft larynx	
Hoarseness	Laryngeal lesion (e.g. vocal cord palsy, papilloma)	
Acute airway obstruction	Retropharyngeal abscess Tonsillitis Glandular fever Foreign body Epiglottitis Croup Bacterial tracheitis	
Dysphagia and feeding difficulties	Epiglottitis Tonsillitis Retropharyngeal abscess	NB Feeding affected with many causes of severe airway obstruction
Apnoeas	Tracheobronchomalacia	

PATTERN OF STRIDOR

Stridor is seldom constant. Any variation can help pinpoint the cause, though asking parents about the timing of stridor in the respiratory cycle is seldom profitable. Typically, laryngomalacia – as with other laryngotracheal causes of stridor – is better when the child is at rest or asleep but made worse by crying, feeding and excitement. Upper airway obstruction at the level of the pharynx is in contrast worse when the child is asleep and is associated with stertor. Airway obstruction greatest in a supine position can occur with a pedunculated laryngeal mass but more often is due to supralaryngeal obstruction such as micrognathia and resultant tongue base occlusion. Improvement in the airway with crying occurs in significant nasal obstruction such as bilateral choanal atresia.

ASSOCIATED FEATURES

Airway obstruction may be associated with a number of symptoms (Table 28.1) alongside stridor including apnoeas, cyanosis, 'dying spells', cough and hoarseness and increased work of breathing (dyspnoea, tachypnoea, recession, nasal flaring, head bobbing). Apnoeic episodes associated with cyanosis are typical of severe tracheobronchomalacia and are sometimes termed 'dying spells'. They may also be described as apparent life-threatening events (ALTEs) of which airway pathology is one of several causes. A newer potential label of 'brief resolved unexplained event' (BRUE) has also been proposed.[1] Parents will usually attempt resuscitation if these episodes are severe. It is often unclear how many of these attacks are otherwise self-limiting.

Tachypnoea and dyspnoea are not limited to upper airway obstruction but a clear description of exertional dyspnoea in an older child provides a useful functional assessment of severity. Cough is typical of tracheo-oesophageal fistula (TOF) and tracheomalacia and is rarely due to 'infantile asthma'. Hoarseness suggests a laryngeal lesion such as papillomatosis and also occurs in vocal cord palsy.

FEEDING HISTORY

Feeding is one of the most strenuous activities for a neonate and is closely connected with breathing. It is therefore vulnerable to compromise in upper airway pathology. A change in feeding or inability to feed is typically keenly noted by carers and is likely to be a key indicator of upper airway status.

An accurate picture of the feeding pattern must be obtained. Breastfed babies with airway obstruction will characteristically 'come up for air'; bottle-fed babies may require thickened feeds or a 'slow teat' (i.e. one with small holes). Aspiration suggests vocal cord palsy, tracheo-esophageal fistula, neuromuscular pathology or rarely a laryngeal cleft. Significant repeated aspiration may be associated with recurrent chest infections. Regurgitation ('posseting') is common in neonates and by itself may not represent significant gastro-oesophageal reflux. The end result of poor feeding may just be slow feeding which

troubles the carers more than the child or there may be failure to thrive with demonstrably poor weight gain. It is important not to assign failure to thrive to the common cause of laryngomalacia without first having considered and excluded other causes. Formal mapping of weight gain in a growth chart is useful in both the assessment of severity and planning of appropriate management. Figure 28.4 demonstrates an example of growth failure as might be seen in a case of significant prolonged upper airway obstruction.

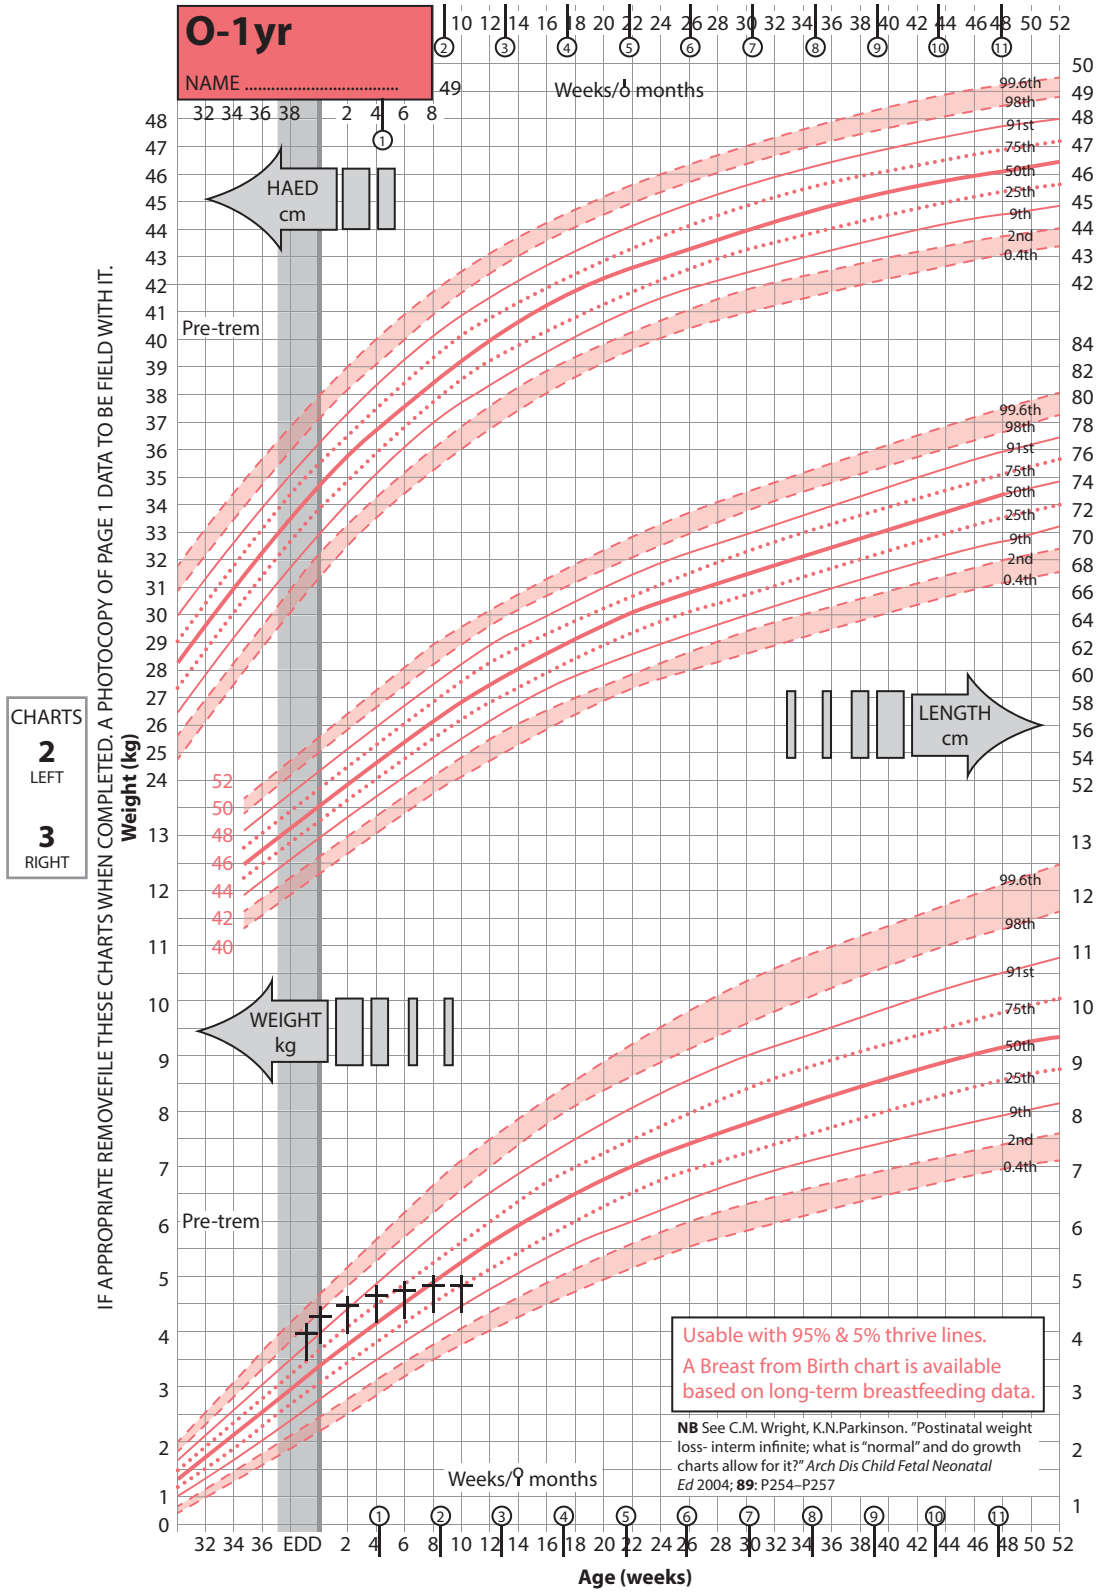

Figure 28.4 Growth chart demonstrating growth failure in the first 3 months of life. (Baseline data Child Growth Foundation.)

GENERAL MEDICAL CONDITIONS

Enquiry into the general past medical history may explain a vocal cord palsy occurring as a result of neurological disease or cardiothoracic surgery. It may also suggest vascular compression associated with congenital cardiac disease. The presence of any skin lesions is important; a cutaneous haemangioma may be associated with a subglottic haemangioma.

ACUTE OBSTRUCTION

In acute airway obstruction the history is taken in parallel with the examination and resuscitation. Take particular note of any possible foreign body aspiration or concurrent illness history. Rapid progression of airway obstruction typically occurs in acute infection and in foreign body inhalation.

Boxes 28.1, 28.2 and 28.3 give examples of congenital and acquired causes of upper airway obstruction and highlight the common pathologies.

Examination

OBSERVATION

Observing the child at rest before proceeding to formal examination provides not only an initial assessment of the degree of respiratory distress and the characteristics of any stridor but also gives time to gain the child's confidence. The characteristics of the stridor need to be observed as well as the effects of airway obstruction such as recession. An abnormal voice, wheeze or cough is a useful localizing sign. The site of the abnormal vibration can rarely be pinpointed with the aid of a stethoscope due to the variable transmission of sound through the thorax.

BOX 28.1 Examples of naso- and oropharyngeal causes of upper airway obstruction (bold = common causes)

Congenital	Acquired – neonates	Acquired – children
Choanal atresia	**Neonatal rhinitis**	**Allergic rhinitis**
Choanal stenosis		**Adenoiditis**
Mid-nasal stenosis		**Adenotonsillar hypertrophy**
Piriform aperture stenosis		**Foreign body**
Glioma		Non-allergic rhinitis
Encephalocoele		Retropharyngeal abscess
Meningocoele		Infectious mononucleosis
Dermoid/teratoma		Ludwig's angina
Craniofacial abnormalities		Thermal and caustic burns
Micrognathia – glossoptosis		
Lingual thyroid		
Lymphovascular malformation		

BOX 28.2 Examples of laryngeal causes of upper airway obstruction (bold = common causes)

Congenital	Acquired – neonates	Acquired – children
Laryngomalacia	**Intubation trauma**	**Intubation trauma**
Vocal cord palsy	Surgical trauma (e.g. laser)	**Croup**
Laryngeal stenosis	Laryngeal stenosis	**Recurrent respiratory papillomatosis**
Laryngeal cysts	Arytenoid fixation	Hereditary angioedema
Webs	Reflux laryngitis	Epidermolysis bullosa
Laryngeal atresia		**Foreign body**
Vallecular cyst		Dislocated arytenoid
Arytenoid fixation		**Epiglottitis**
Posterior laryngeal cleft		Trauma – fracture
		Caustic and thermal burns
		Haemangioma
		Lymphovascular malformation

BOX 28.3 Examples of tracheal causes of upper airway obstruction (bold = common causes)

Congenital	Acquired – neonates	Acquired – children
Tracheal stenosis	**Post- intubation/ instrumentation/ tracheal stenosis**	**Croup**
Tracheal atresia	Reflux tracheitis	Bacterial tracheitis
Trapped first tracheal ring		**Foreign body**
Complete rings		Localized malacia secondary to a tracheostomy or TOF repair
Micro (stovepipe) trachea		Thyroid masses
Haemangioma		Lymphovascular malformation
Primary tracheomalacia		Mediastinal tumours
Secondary tracheomalacia – vascular compression		

Auscultation is, however, useful to detect abnormal heart sounds and wheeze.

With rapidly advancing technology, it is increasingly commonplace for carers to have mobile devices with audiovisual recording capabilities. Useful information can sometimes be obtained from reviewing a parental recording of a symptomatic episode.

The pre-endoscopy assessment, though important, can be only a guide to the type and degree of pathology discovered at endoscopy. The combination of a thorough history, examination and limited investigation can in some

conditions (e.g. suspected mild laryngomalacia) provide sufficient diagnostic probability to give a working diagnosis and avoid progression to immediate endoscopy by default. The type of stridor may be characteristic of a particular pathology but is never diagnostic.[2] A second pathology alongside laryngomalacia may be present in up to 20% of cases though few will require treatment.[3] The diagnosis can only be confirmed by endoscopic evaluation. This does not mean that every child with stridor requires laryngotracheobronchoscopy. In most children seen in a secondary or tertiary referral centre, endoscopy will be required and in most conditions is the gold standard.

ASSOCIATED FEATURES

Subcostal, intercostal and suprasternal recession may occur separately or together and also be associated with 'see-saw' respiration. The severity of recession is a better indicator of the severity of airway compromise than the degree of stridor. Accessory muscles of respiration are not usually employed by the younger child, who depends predominantly on diaphragmatic movement. Nasal flaring and head bobbing are important and concerning signs, as is abnormal posturing; the child may adopt a position of neck extension and, in some instances, head rotation with airway obstruction as the position of greatest comfort.

The volume of stridor can paradoxically reduce as the obstruction increases due to the diminishing airflow. No comfort should be taken from the fact that a child still looks pink. Cyanosis is a very late event and suggests obstruction has been severe or prolonged.

If a supralaryngeal component is suspected, nasal patency should be assessed with a metal instrument or mirror, a wisp of cotton wool or using the bell end of a stethoscope. Make a conscious assessment of jaw and tongue size. Examine the ears, nose, throat and lastly neck with the usual caution that you must not use any instrumentation to examine the throat of child in whom pathology such as epiglottitis is suspected. Observing the child attempting to feed may be extremely valuable, particularly if there is a feeding or aspiration concern.

Investigations

Investigations need to be carefully selected on the basis of the history and examination. They may be categorized into pre- and postendoscopy investigations.

IMAGING

The value of radiological investigations was reviewed retrospectively by Tostevin et al.[4] Plain anteroposterior (AP) and lateral views of the neck, digitally enhanced to demonstrate the subglottis, oropharynx and nasopharynx, are rapid, inexpensive tests that do not require sedation or anaesthesia. The term 'Cincinatti view' describes a high-kilovolt filter AP film designed to highlight the soft tissues of the neck.

A chest radiograph may include the upper trachea and larynx in the smaller child, otherwise a separate AP neck film may be obtained. This can demonstrate the 'steeple sign' of croup and bulky lesions such as subglottic cysts, papillomata. Significant stenosis may also be delineated. A plain chest radiograph may show the ground-glass appearance of bronchopulmonary dysplasia or mediastinal shift resulting from a foreign body. If a foreign body is suspected in young children, diaphragmatic screening with videofluoroscopy is a more sensitive technique. In older children, inspiratory and expiratory films may demonstrate diaphragmatic immobility on the side of the obstruction. Foreign bodies that do not cause complete lower airway obstruction, those that are radiolucent and those located in the larynx represent particular diagnostic challenges.[5]

Airway fluoroscopy has been found to be highly specific in the diagnosis of both laryngotracheomalacia and fixed airway lesions, but its sensitivity is poor; it has not been proven to be a useful screening tool.[6] Airway fluoroscopy can be combined with a contrast swallow looking for vascular compression and aspiration. Contrast swallows are of limited diagnostic value in the investigation of paediatric stridor and may be best employed following endoscopy, particularly in cases in which a vascular ring or tracheo-oesophageal fistula is suspected.[7]

Bronchography may be performed using non-ionic contrast media. It requires expertise and is associated with risk, particularly in infants and those prone to apnoea. It is particularly useful for the lower airway, demonstrating tracheobronchial stenosis and malacia.[8] Opening pressures of the collapsed bronchi and lower trachea can be measured and used to determine the level of airway support needed.

Echocardiography can be used in cases of suspected vascular compression, demonstrating most but not all abnormal vasculature as well as coincidental or symptomatic congenital heart disease.[9] With experience, ultrasound of the vocal cords can be used to demonstrate vocal cord palsy with reasonable accuracy.[10] Laryngeal ultrasound may also demonstrate structural lesions such as cysts, polyps and papillomata; however, it is non-diagnostic.

Both computerized tomography (CT) and magnetic resonance imaging (MRI) can demonstrate the configuration of thoracic vasculature in cases of extrinsic tracheal compression and thus are particularly useful postendoscopy. CT and MRI may also aid in the evaluation of airway lesions although they are not usually sufficiently sensitive to fully characterize a lesion or stenotic segment. Helical or multidetector CT with multiplanar and 3D reconstruction offers increasingly better definition of fixed tracheal lesions, which are effectively 'virtual bronchoscopy'.[11, 12] Dynamic changes – primary and secondary tracheobronchomalacia – are not well evaluated by cross-sectional imaging. The degree, maturity and mucosal quality of a stenosis can be more accurately assessed at endoscopy.

Imaging may not be appropriate in situations of acute and severe upper airway obstruction. Should imaging be agreed to be of diagnostic and constructive use, it must be performed with close medical supervision so that the airway can be monitored and intervention provided in the event of deterioration.

RESPIRATORY FUNCTION TESTS

Lung function tests such as flow-volume-loops provide a graphical representation of inspiratory and expiratory flow. This can help to localize the site of obstruction; it may differentiate between intra- and extrathoracic obstruction and between fixed and variable pathologies. Other lung function tests such as peak flow testing may be best selected and reviewed with the advice of a pulmonologist. These tests require a degree of patient cooperation and are non-diagnostic. They may, however, assist in the assessment of severity, decision-making regarding management and monitoring of clinical progress.

Polysomnography or 'sleep studies' are also not often used in the assessment of the stridulous child. Airway obstruction that worsens during sleep is usually a feature of pharyngeal obstruction such as adenotonsillar obstruction or a craniofacial anomaly. Laryngomalacia and most laryngotracheal pathologies are rarely worse during sleep.

ASSESSMENT OF REFLUX

It is difficult to gauge whether reflux is secondary to airway obstruction with negative intrathoracic pressure drawing gastric contents into the oesophagus or if the reflux is a separate entity. Occasionally, reflux may be a primary causative factor with secondary reflux laryngitis.

Gastro-oesophageal reflux[13, 14] can be assessed with a radiopaque contrast study, milk scan (nuclear medicine), pH study or endoscopy. Contrast studies have low specificity and sensitivity and are dependent on positioning and radiological interpretation. The other investigations are more sensitive but are usually interpreted by gastroenterologists looking for reflux into the lower oesophagus. The laryngologist is interested in the pH in the upper oesophagus and pharynx, which can be measured using a second probe in the upper oesophagus. Episodes of reflux occur without an associated pH change. These events may be detected by impedance testing (multiple intraluminal impedance); this newer technique is, however, more expensive and less widely available.[15]

Reflux is considered in detail in Vol 3, Chapter 77, Reflux Disease.

Endoscopy

The two principal concerns in paediatric upper airway endoscopy are safety and diagnostic accuracy. To achieve these objectives requires not only a full range of specialized paediatric endoscopy equipment (**Box 28.4**) but, most significantly, a high level of experience in the endoscopist, anaesthetist and nursing staff. A systematic approach will provide a diagnosis in most cases.[16]

AWAKE FLEXIBLE ENDOSCOPY IN THE OFFICE/WARD

The introduction of ultra-thin endoscopes with good optics and a diameter of less than 2 mm has allowed even neonates to be evaluated without the need for a general anaesthetic.[17, 18] Peroral passage of an endoscope may be performed in the edentulous neonate using a finger between the gums to protect the instrument. This alternative approach is preferred by many to transnasal introduction in the young infant.[19]

Flexible laryngoscopy may be considered a diagnostic screening procedure. The view, particularly of the larynx, is often suboptimal. No invasive diagnostic or therapeutic procedure can be undertaken and, even if an abnormality is demonstrated (such as laryngomalacia), a second pathology can be missed. Awake flexible endoscopy is particularly useful to assess dynamic abnormalities such as vocal cord palsy. Flexible endoscopy under sedation in an endoscopy suite is widely practised by paediatricians and pulmonologists and is becoming more popular with otolaryngologists as an adjunct to rigid endoscopy.[20]

Awake flexible endoscopy is most feasible in the infant who may be swaddled (under 9–12 months) and in the older, cooperative child. Office-based flexible endoscopy of the lower airway to the level of the carina has also been described as feasible and safe in a paediatric population although this practice is not widespread.[21]

BOX 28.4 Suggested minimum equipment standards for paediatric airway endoscopy

- Adjustable laryngeal suspension system
- Operating microscope with 400f lens
- Selection of age-appropriate paediatric laryngoscopes of varying size and with a variety of viewing angles
- Dedicated laryngeal microsurgical instruments, e.g. microscissors, probes, cupped and straight forceps
- Selection of age-appropriate ventilating bronchoscopes with Hopkins rod telescopes to fit
- Suitable light source with fibre-optic cable
- Camera and monitor with image-capture facilities – video and still
- Colour printer
- Selection of forceps for the removal of foreign bodies
- Optical forceps with rigid telescope(s) of corresponding length
- Selection of fibre-optic bronchoscopes and a nasopharyngoscope
- Full range of paediatric tracheostomy tubes

LARYNGOTRACHEOBRONCHOSCOPY

Laryngotracheobronchoscopy (**Figure 28.5**) is the gold standard in the assessment of the stridulous child. It is a highly technical procedure. The whole team (surgeon, anaesthetist and nursing assistant) need to work closely together to perform the examination safely, and to optimize the assessment. The advent of video and high-quality image reproduction on a viewing monitor has been invaluable in training and teamworking. The anaesthetist and theatre team may also view the live image and may be able to anticipate interventions required.

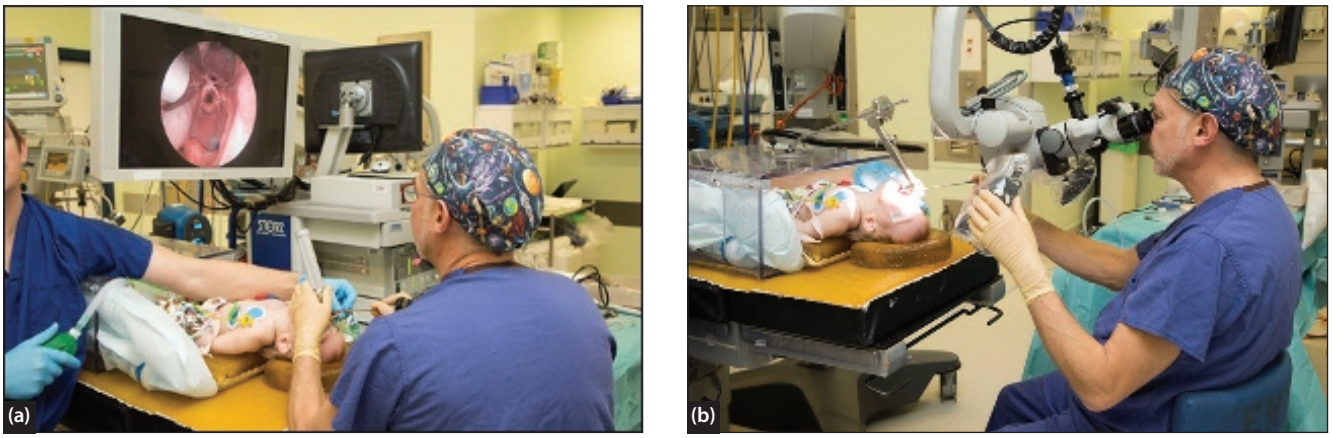

Figure 28.5 Laryngotracheobronchoscopy. (a) Handheld laryngoscope and Hopkins rod technique. **(b)** Supension laryngoscopy and microscope technique.

ANAESTHESIA FOR UPPER AIRWAY ENDOSCOPY

Major units around the world use a variety of techniques; it is probably more important that a theatre team work together effectively than that one particular technique is followed. High levels of cooperation and skill are required. Practice varies between centres as to whether intubation is used at the start of the procedure, however most units would now use spontaneous respiration rather than paralysis. Spontaneous respiration has much to recommend it as a technique: it maintains muscle tone, promotes gas exchange and is essential to detect dynamic conditions.

Induction

Some units will use a premedication such as atropine or glycopyrrhonium bromide to facilitate a dry surgical field and improve the efficacy of topical anaesthesia. Pre-operative steroids are a good safeguard if significant stenosis or likelihood of increased inflammation is suspected. Intravenous induction is preferable for older children; gas induction is best in infants, younger children, those with poor venous access and those with a precarious airway. Topical local anaesthetic spray (typically lignocaine) should be applied to the vocal cords when the anaesthetic level is sufficiently deep for this to be tolerated. This amount needs to be carefully measured as the preparations used in adults can easily result in overdosage.[22, 23]

Maintenance of anaesthesia

Two principal anaesthetic techniques are used for general anaesthesia with spontaneous respiration: maintenance with a volatile agent (e.g. sevofluorane) and total intravenous anaesthesia (TIVA) with an infusion such as propofol and remifentanil.[24]

A volatile agent and oxygen mix can maintain a level of anaesthesia that allows a thorough examination in a child who is breathing spontaneously. Sevoflurane is non-irritant to the airway and has the advantages of rapid onset and no pungency, allowing immediate delivery of high concentrations. This advantage of rapid induction may be offset by rapid termination of effect during periods of relative hypoventilation or airway obstruction. Now superseded by sevofluorane, halothane gas was also useful for this purpose. The anaesthetist needs to be able to control anaesthesia in response to surgical conditions and for this a video monitor visible to the anaesthetist is invaluable.

Airway tube technique

An endotracheal tube may be used as a nasopharyngeal airway or 'prong' to provide oxygen and volatile anaesthetic agent, if used. Should transnasal passage not be possible, an oropharyngeal tube may be used, placed at the angle of the mouth. A significant advantage of a non-intubation technique is that the endoscopist has a view of an airway that has not been altered by the passage of an endotracheal tube. Confusion relating to lesions caused by intubation for the procedure cannot occur and at any time airway control can be regained with intubation or the use of a bronchoscope.

An alternative technique is to intubate the child prior to withdrawal of the tube for endoscopy. This technique is not routinely used in our institutions. Intubation does facilitate rapid progress to the required level of anaesthesia. Nasotracheal intubation allows the endotracheal tube to be withdrawn into the nasopharynx once the child is breathing spontaneously. Careful positioning of the tube over the glottis by the endoscopist can also achieve good oxygen and volatile agent provision, when required.

Jet ventilation

This technique allows the child to be paralysed, preventing coughing and gagging. Gas exchange is maintained by short pulses of oxygen and anaesthetic gas. Subglottic jet ventilation may be provided in adults using a transglottic cannula but this is not only impractical but also risks barotrauma (pneumothorax and air trapping) in children. Supraglottic jet ventilation has been described although few centres use this technique.[25] Dynamic conditions such as malacia and cord palsy cannot be well identified.

Laryngeal mask airway

A laryngeal mask airway (LMA) is useful for fibre-optic tracheobronchoscopy, particularly if the patient is difficult to intubate because of mandibular hypoplasia.[26]

LARYNGOTRACHEOSCOPY TECHNIQUE

The following description assumes that the patient may have been intubated, suspension laryngoscopy is employed and that the larynx and/or trachea is to be examined with a rigid telescope or microscope.

A small sandbag or pad is usually required under the shoulders with sandbags laterally to support the head if required. A Mayo table supports the laryngostat (laryngeal support) clear of the chest.

It is important to prepare and check all equipment prior to the endoscopy so that the endoscopist is fully prepared for all eventualities. The range of Hopkins rod rigid endoscopes should include all lengths and diameters that could be needed. A 30° telescope may be able to better assess the supraglottic larynx without splinting. A microscope should be available, though is often not used unless surgical intervention is required when two hands are needed for manipulation. If a microscope is used, a 400 mm lens allows the use of standard laryngeal instruments but a 350 mm lens brings the patient closer, allowing easier laryngeal manipulation, which is particularly important in small neonates. For routine examination, the Hopkins rod and camera can be held in the left hand with a probe used in the right. The image quality available using a rigid endoscope is far superior to that of the microscope. Every unit should have a chart listing the appropriate sizes of bronchoscope for different ages. The age-appropriate bronchoscope should be checked and one at least a size smaller instantly available as well.

Laryngeal examination is usually begun by gently inserting the lubricated suspension laryngoscope, taking care to protect the teeth and lips and to keep the tongue central to provide a well-centred view. As in adults, it is important to check the overall appearance of the pharynx and supraglottis during introduction of the laryngoscope. The endotracheal tube, if present, is followed to the tip of the epiglottis. The epiglottis should be gently lifted forward making certain that it does not curl up in front of the laryngoscope preventing a complete view of the anterior commissure. An overall assessment of the larynx can be made with a tube *in situ*, providing a degree of stability that is particularly welcome in the child with a compromised airway.

Laryngeal examination with the endotracheal tube removed provides a superior view and, by using a probe to move the arytenoids independently, the mobility of the cricoarytenoid joints can be assessed. If an interarytenoid scar is present, the arytenoids will not move independently. A posterior laryngeal cleft is excluded by passing the probe between the arytenoids, comparing the lower limit of the interarytenoid groove with that of the posterior commissure. Finally, great care should be taken to pass through the vocal cords if a rigid endoscope is used to inspect the subglottis.

The time available for the examination will depend on the airway and respiratory reserve. In a child breathing spontaneously with a normal airway and normal lung function, anaesthesia can be maintained solely by the use of inhalational or intravenous agents and a nasopharyngeal airway. In some cases the time may be very limited and it is essential to be prepared to move ahead with bronchoscopy at any stage. If there is significant subglottic stenosis, an ultra-fine telescope passed through the laryngoscope will cause less trauma than a bronchoscope.

BRONCHOSCOPY TECHNIQUE

Traditionally, a ventilating bronchoscope (**Figure 28.6**) has been used which provides a means of actively ventilating the patient if required. With spontaneous ventilation, a smaller diameter rigid Hopkins rod telescope can be used with less trauma and reduced splinting of the airway.

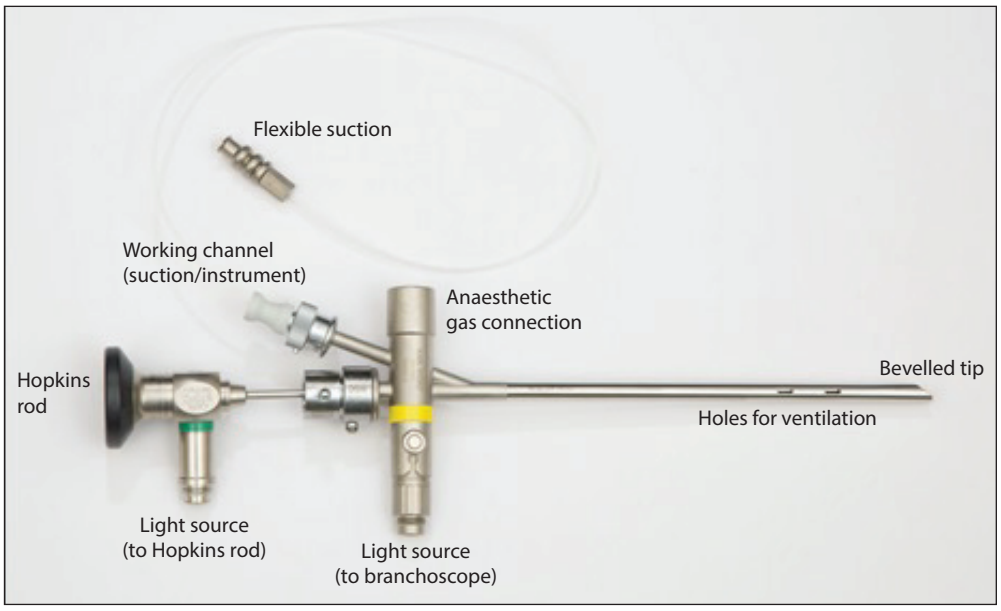

Figure 28.6 Ventilating bronchoscope and Hopkins rod.

An anaesthetic laryngoscope can be used in the vallecula to lift the larynx forward while passing either the tip of the Hopkins rod or the bevel of the bronchoscope through the vocal cords. If a bronchoscope is used, this can be performed under video control with a Hopkins rod coupled into the bronchoscope. Tracheomalacia should be observed with a small bronchoscope withdrawn from the area in question and without positive airways pressure to avoid splinting.

The subglottis, trachea, the carina and main bronchi are all systematically examined and videographs or digital images recorded. Photodocumentation of the endoscopic findings and printing of a compilation of images not only benefits the patient record but also is a useful visual tool for explaining findings to the family. A minimum of a 'four-shot view' of the supraglottis, glottis, subglottis and trachea, and lastly of the carina and main bronchi is suggested. Video recording of dynamic pathologies such as abnormal vocal cord movement, laryngomalacia and tracheobronchomalacia is also recommended.

It is vital that accurate records are kept. Use of a standardized data capture form facilitates this.[27] This provides an invaluable source of information for sequential clinical comparisons, medicolegal purposes and teaching. Use of a recognized staging system is important for research purposes, collaboration and publication of results.

DYNAMIC ASSESSMENT OF THE LARYNX ON RECOVERY FROM ANAESTHESIA

Typically, this can be achieved by withdrawal of the bronchoscope to just posterior to the tip of the epiglottis. This gives a good view of the vocal cords to exclude a cord palsy and of the arytenoids to exclude the common posterior form of laryngomalacia, though anterior collapse of the epiglottis may be masked. In this case, a 30° telescope can be used. The anaesthetist should describe the phase of respiration to enable the endoscopist to check for paradoxical vocal cord movements.

Techniques for dynamic assessment of the vocal cord movement are to insert a laryngeal mask with a fibreoptic bronchoscope passed through this to just above the laryngeal inlet or passage of the scope through a specially adapted face mask.[28] If a bilateral vocal cord palsy is suspected and structural abnormalities have been excluded with a full microlaryngoscopy and rigid bronchoscopy, it is sometimes necessary to reschedule the patient for a further examination in which a laryngeal mask and fibreoptic scope are used from the outset, reducing the influence of prolonged anaesthesia on the cord function.

MANAGEMENT OF ACUTE AIRWAY OBSTRUCTION

In the acute situation, assessment, history taking and resuscitation will often proceed in parallel. In the example of a child arriving in the emergency room with suspected croup, the physician will be assessing the child for the degree of airway obstruction by gauging the recession and dyspnoea at the same time as asking the parent/carer for the length of history and whether there is any possibility of foreign body inhalation. A nurse may be checking the oxygen saturation and setting up humidified oxygen. Another member of the team may have to call and alert the operating room that the child may need intubation as well as calling the anaesthetist and otolaryngologist. This situation clearly benefits from careful planning, with most units having a protocol for how to deal with the stridulous and airway-compromised child. The protocols vary considerably, with some units insisting on the presence of an otolaryngologist at intubation in case a tracheostomy is needed while others have managed for many years without.[29, 30]

In a child with a compromised but functional airway it is crucial that upsetting the child does not cause deterioration. Coughing, crying and distress may result and change obstruction from partial to complete. Significant consideration and skill are required in the management of such a patient. The child should be kept in a position of comfort with its carers in a calm environment and the applications of adjuncts such as pulse oximetry, oxygen and nebulized adrenaline carefully tailored. Interventions such as venepuncture, taking of radiographs and flexible nasendoscopy may jeopardize the critical airway.

Medical management

OXYGEN THERAPY

With an obstruction to airflow and normal alveolar function, raising the concentration of inspired oxygen will reduce the ventilatory requirement to maintain adequate oxygen saturation levels but will not aid carbon dioxide clearance. So long as the possibility of hypercarbia is appreciated, oxygen is a useful drug in the treatment of airway obstruction.

As previously emphasized, a face mask applied to the conscious child is likely to be upsetting and should be avoided. Use of nasal cannulae, wafting or 'head box' oxygen may be better options. Persistent hypoxia and cyanosis are very late signs in a child and are likely to precede rapid respiratory collapse.

HUMIDIFICATION

There is no objective evidence that raising the humidity of the inspired air is beneficial in upper airway obstruction and in croup.[31,32] Humidification has however been used for decades but few units still use humidity tents or 'croupettes' as these have the disadvantage of decreased visibility and may also frighten the child.

HELIUM-OXYGEN MIXTURES (HELIOX®)

Addition of helium to inspired gases is associated with a reduction in the turbulence of flow. Helium–oxygen mixtures are thus recognized to decrease airway resistance and have been used for several decades in the management of patients with upper airway obstruction.[33] Use of 70% helium/30% oxygen inhalation has been systematically

reviewed for use in treatment of croup in children; there is some evidence to suggest a short-term benefit in moderate to severe croup.[34]

PHARMACOTHERAPY

Intravenous and oral steroids such as dexamethasone have been shown to be beneficial in croup, with inhaled steroids having a similar effect.[35] Klassen summarizes: 'All children with croup symptoms who demonstrate increased work of breathing in the clinics or emergency departments should be treated with glucocorticoids.'[36] This treatment may be with nebulized budesonide (2 mg) or oral or intramuscular dexamethasone (the optimal dose needs to be defined; 0.15–0.6 mg/kg has been described). Oral glucocorticoids such as dexamethasone and prednisolone may be the best options due to ease of administration, widespread availability, and lower cost. Inhaled or nebulized budesonide can be used at home for children with recurrent croup.[35]

Nebulized adrenaline (400 µg/kg or 0.4 mL/kg of 1 : 1000 to a maximum of 5 mL) may result in a transient improvement within 10-30 minutes, lasting up to 2 hours. This should be considered in pathologies that have an inflammatory component, such as croup, with moderate or severe distress.[37] Again, a nebulizer should be applied only if it does not increase the distress of the patient.

Transfer of the child with stridor

Transfer of a seriously ill child with stridor to a centre of anaesthetic and surgical expertise may be necessary. The Advanced Paediatric Life Support (APLS) framework teaches that the right child should be taken at the right time, by the right people, to the right place, by the right form of transport, and receive the right care throughout.[38] This is often best achieved by a specialized children's retrieval team with advanced life-support capabilities.

It may be necessary and appropriate for the airway to be secured by intubation prior to transfer. Short-term placement of an LMA may be an alternative in cases where intubation is not possible.

The systematic approach requires preparation and planning for transfer. Frequent reassessment of the child by appropriately skilled staff is vital. Continuous monitoring should also be used where possible: oxygen saturations, pulse, arterial pH and gases, temperature, blood pressure, carbon dioxide monitoring (if intubated).

Surgical management

The increasing use of intubation as an alternative to tracheostomy in acute airway obstruction has been brought about by advances in anaesthesia and paediatric intensive management coupled with the appreciation that paediatric tracheostomy, even in the short term, can be associated with significant morbidity and potential mortality. Intubation may not be possible in all cases, despite anaesthetic skill, careful planning and monitoring. Severe subglottic stenosis, impacted foreign bodies and advanced epiglottitis are key examples; rarer conditions such as laryngeal atresia with ventilation being achieved via a tracheo-oesophageal fistula also necessitate a tracheostomy.

It is this uncertainty combined with the precipitate nature of paediatric airway obstruction that makes it mandatory in most hospitals for an ENT surgeon to be informed if a child with airway obstruction of unknown aetiology is to be intubated. Depending on the circumstances, it may be necessary to have an emergency tracheostomy set open with a tube of the correct size already selected.

Once the child has been slowly induced with a volatile anaesthetic agent it is possible to inspect the larynx and exclude epiglottitis. This may be all that is required; it may be possible to manage the child using a nasopharyngeal airway (prong) and/or continuous positive airway pressure (CPAP). If intubation is required, it is important to minimize any damage to mucosa that may already be inflamed; very gentle intubation with a small tube just large enough for adequate ventilation and suction of secretions is recommended. Even if an initial intubation is oral, which tends to be easier, the tube should be replaced with a nasal tube; this may be more secure and better tolerated. The sizing of the tube can be assessed by checking for a leak and the tracheobronchial secretions suctioned. If the secretions are very tenacious or there is still an element of airway obstruction, a ventilating bronchoscope should be passed to exclude bacterial tracheitis or a foreign body.[39,40] Significant tracheobronchomalacia is another reason for continuing airway difficulty after intubation and this will usually respond to CPAP.

EMERGENCY TRACHEOSTOMY

With experienced paediatric anaesthetists, this is now very unusual. Otolaryngologists are often asked to attend a potentially difficult intubation, but are rarely needed. A ventilating bronchoscope may be easier to pass than an endotracheal tube. An endotracheal tube mounted on a Hopkins rod telescope may also be particularly useful in a difficult intubation (**Figure 28.7**). If there is any potential for an emergency tracheostomy, the surgical set and appropriate tube need to be instantly available. It is important to stay strictly in the midline so the child needs to be carefully positioned without neck or head deviation. A finger either side of the larynx is helpful with a vertical incision through the skin and down to the trachea. If a paediatric tracheostomy tube is not available, a paediatric endotracheal tube can be used, ensuring it remains above the carina. Paediatric tracheostomy is described in detail in Chapter 35, Tracheostomy and home care.

'CHAOS' AND 'EXIT'

Advances in the availability and quality of antenatal imaging has led to significant advances in the recognition and treatment planning of children with congenital high airway obstruction syndrome (CHAOS). A significant risk of airway compromise at the time of delivery with associated morbidity and mortality at birth may be avoided by an

Figure 28.7 A Hopkins rod telescope with an endotracheal tube mounted and ready to introduce in a difficult intubation.

ex utero intrapartum treatment (EXIT).[41, 42] This highly specialized technique requires expert multidisciplinary input and is a broad topic with links and overlap with foetal surgery.

In brief, the underlying principle of the technique is to 'operate on placental support'; materno-placental and placento-foetal blood and gas exchange are maintained while the neonate's airway is secured. This is achieved by delivery of the foetal head and upper torso through a hysterotomy incision. Intubation, bronchoscopy, tracheostomy and excision of the obstructing lesion may be performed as permitted and indicated. Naturally, the EXIT technique requires an antenatal diagnosis of the pathology causing CHAOS and multidisciplinary care at a centre of expertise to coordinate this elective surgery.

Parental counselling and consideration of ethical aspects, particularly in the foetus with multiple congenital abnormalities, are of fundamental importance.

BEST CLINICAL PRACTICE

- ✓ In the acute situation, assessment, history taking and active resuscitation may proceed simultaneously.
- ✓ In suspected epiglottitis, instrumentation of the oral cavity and pharynx for clinical examination must be avoided.
- ✓ All children with croup who demonstrate increased work of breathing should be treated with glucocorticoids. Nebulized adrenaline may also be given. **[Grade A]**
- ✓ Wherever possible, endotracheal intubation is preferable to emergency tracheostomy.
- ✓ If a child with airway obstruction of unknown aetiology is to be intubated, an ENT surgeon should be informed. It may be necessary to have an emergency tracheostomy set open with a tube of the correct size already selected although this is very rarely needed.
- ✓ A difficult endotracheal intubation may be facilitated by the use of a small ventilating bronchoscope or by passing a Hopkins rod telescope on which a endotracheal tube has been mounted.

FUTURE RESEARCH

- ➤ The optimal glucocorticoid dose and agent for use in inflammatory upper airway obstruction conditions such as croup is yet to be determined.
- ➤ A growing trend towards specialization within otolaryngology will ensure that airway endoscopy in children is increasingly the remit of otolaryngologists with a special interest and training in this work.

KEY POINTS

- Stridor is the noise from a narrowed airway and is a symptom, not a diagnosis.
- The aim of the history, examination and special investigations is to determine not only the site and cause of the obstruction (the diagnosis) but also its effect on the airway (the severity).
- Hypoxaemia is a late feature of airway obstruction, particularly in children treated with oxygen.
- Improvement in stridor may paradoxically be due to worsening obstruction.
- Laryngomalacia is common but it is important not to assign failure to thrive to this without first having considered and excluded other causes.
- Rapid progression of airway obstruction typically occurs in acute infection and in foreign body inhalation.
- Laryngotracheobronchoscopy is the gold standard in the assessment of the stridulous child and is a highly skilled procedure involving a team approach between anaesthetist, endoscopist and operating room personnel. Adequate facilities are not available in all institutions.

CHAPTER 29

ACUTE LARYNGEAL INFECTIONS

Lesley Cochrane

SEARCH STRATEGY AND EVIDENCE BASE

Data in this chapter may be updated by a search of Medline using the following keywords: croup, acute laryngotracheitis, acute laryngotracheobronchitis, acute epiglottitis, diphtheria, bacterial tracheitis and child. The Controlled Trials Register of the Cochrane Library and the Cochrane Database of Systematic Reviews were also searched. The search was initially restricted to randomized controlled trials and meta-analyses and then widened, focusing on diagnosis, management and immunization.

INTRODUCTION

Laryngeal infection in childhood causes airway obstruction, of which the cardinal symptom is stridor. In the developed world, 'croup' – a clinical scenario characterized by a combination of stridor hoarseness and a typical barking cough – is the commonest (90%) cause of acute airway obstruction in children. Epiglottitis has been the next most common infective cause but is now seen much less frequently due to the widespread introduction of *Haemophilus influenzae* b (Hib) vaccine; bacterial laryngotracheobronchitis and diphtheria are less common. The differential diagnosis of acute acquired stridor includes 'spasmodic croup', retropharyngeal abscess, angioneurotic oedema, neoplasia, acute laryngeal trauma and foreign body aspiration.

In this chapter the various clinical syndromes of acute laryngeal infection are discussed and their distinctive features emphasized. For a number of these conditions several terms have evolved over the years; these are included in the headings for ease of reference but the first term, that most commonly used in the UK, is used in the text. The effects of immunization programmes on the changing patterns of disease are examined. The efficacy of medical treatment and the role of endotracheal intubation and/or tracheostomy for safe airway management in the different conditions are considered.

Good management depends on teamwork involving the primary care physician, the paediatrician, the paediatric otolaryngologist, the paediatric anaesthetist and the paediatric intensive care physician. Multidisciplinary evidence-based protocols should be established and followed to optimize outcomes.

CROUP (ACUTE LARYNGOTRACHEOBRONCHITIS, VIRAL LARYNGOTRACHEOBRONCHITIS)

Croup typically presents as a clinical syndrome of hoarseness and a distinctive barking cough progressing to inspiratory or biphasic stridor. There is usually a preceding history of upper respiratory tract symptoms, malaise and pyrexia. Children with croup do not typically drool or appear toxic, in contrast to children presenting with epiglottitis. The symptoms are thought to be due to mucosal oedema of the larynx and trachea following a viral illness. Croup is classically caused, but not limited to, infection with **parainfluenza virus type I**. Other causative

viruses include: **parainfluenza virus type II, respiratory syncytial virus (RSV) virus types A and B** and **rhinovirus.**[1] Due to improving methods of detection, an increasing variety of viruses are being implicated in the cause of croup including *Metapneumovirus, Coronavirus* and most recently *Bocavirus* in Korea with less predominance of parainfluenza type I.[2, 3] Croup usually affects children between 6 months and 3 years of age with a peak incidence in 2-year-olds.[1] Boys are more commonly affected than girls.[1, 4] There is a seasonal variation: in the USA and in Canada a minor peak in hospital admissions for croup has been noted in February and a peak in the autumn in odd numbered years, coinciding with biennial epidemics of human parainfluenza type I infection.[4, 5] In Australia, seasonal variation has also been observed.[6] Although croup is a self-limiting illness, it is a large burden on healthcare systems due to frequent visits to doctors and accident and emergency rooms. The annual incidence of croup in children younger than 6 years ranges from 1.5% to 6%.[1]

The diagnosis of croup is a clinical one and laboratory tests and radiological tests are generally not needed. In severe cases, however, if there is a diagnostic dilemma, a radiograph of the thoracic inlet will show characteristic narrowing of the subglottis on an anteroposterior view ('steeple' or 'pencil-tip' sign) (**Figure 29.1**).

There are inflammatory changes throughout the airway in croup but the critical symptom of stridor is due to oedema in the subglottis, the narrowest part of the paediatric airway. Just 1 mm of oedema in an 18-month-old child with a subglottic diameter of 6.5 mm will reduce the cross-sectional area by approximately 50%. Laminar airflow (proportional to the fourth power of the radius – 'Poiseuille's law') is thus greatly reduced. Some children are more at risk of severe symptoms than others; factors predisposing to severe symptoms include pre-existing subglottic or tracheal narrowing, chronic lung disease and airway reactivity, characterized by a history of inhalant or food allergies.[7]

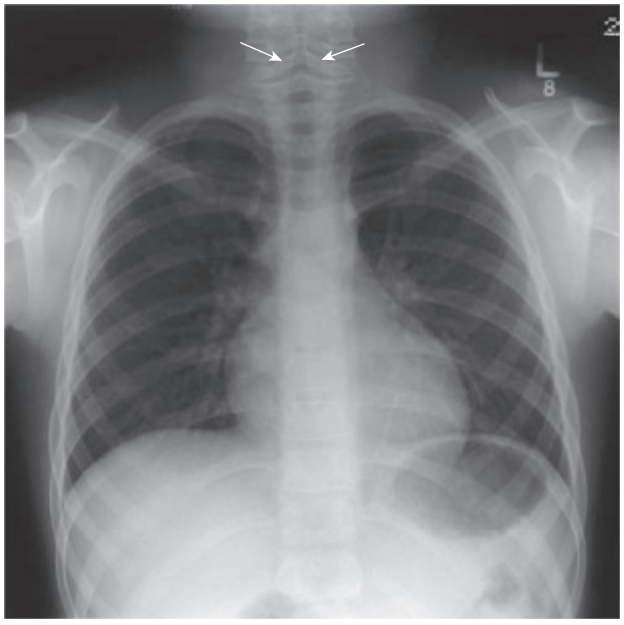

Figure 29.1 'Steeple' or 'pencil-tip' sign. Narrowing of the subglottic airway owing to mucosal oedema in croup (arrows). Image courtesy of Ben Hartley.

Croup is usually self-limiting; 50% of children improve within 24 hours of the onset of symptoms, and most recover within 4 days without treatment. Airway symptoms can become serious and life-threatening in rare cases. Mortality, however, is rare, with an estimated overall mortality of 1 in 30 000 cases in a large review.[8]

It is important to consider congenital or acquired mild subglottic stenosis in the differential diagnosis of infants presenting with 'recurrent croup'. In persistent cases endoscopy is mandatory.[9]

The management of croup consists of minimal disturbance while assessing the severity of the croup and guiding treatment accordingly. Croup severity can be classified using the Westley Croup Score (**Table 29.1**). The scoring system is based on five clinical features of croup (inspiratory stridor, retraction, air entry, cyanosis and level of consciousness). It has been clinically and radiologically validated, the total score correlating with the diameter of the tracheal lumen. A maximum score is 17, a score of 2–3 equates to mild croup, 4–7 to moderate croup and 8 or more to severe croup.[10] The scoring system is widely used in studies, although some authors report that it is less commonly used in daily clinical practice due to interobserver variance.

For mild croup, treatment can be supportive, with reassurance of both carers and child, and observation and monitoring of the child's symptoms, but without separating the child from its carer(s) as this will increase anxiety. Sedation is not advised because of the risk of respiratory depression, although chloral hydrate 30 mg/kg has been advocated if sedation seems necessary. Traditionally, it has been recommended that children with croup should be nursed in a humidified environment or mist tent; there is no evidence that this is of clinical benefit although it may be soothing.[11]

Corticosteroids

The mainstay of treatment for croup is corticosteroids. Corticosteroids have a systemic anti-inflammatory effect. There is a reduction in capillary endothelial permeability and therefore in mucosal oedema, and stabilization of lysosomal membranes, decreasing the inflammatory reaction. Topical corticosteroids theoretically have the added benefit of causing local alpha-mediated vasoconstriction. A number of studies have looked at clinical improvement after corticosteroid therapy. Clinical benefit can be measured by an improvement in croup score, reduced hospital admission rates, shorter length of stay, lower intubation rates or a reduced need for cointerventions such as the administration of epinephrine nebulizers.

In 2011, a Cochrane systematic review of the use of glucocorticoids in the treatment of croup analysed the results of 41 studies. The review concluded that, when compared to placebo, treatment with glucocorticoids resulted in a significant clinical improvement within

TABLE 29.1 Croup score based on Westley system (reprinted from Westley et al.,[10] with permission)

Score	0	1	2	3	4	5
Inspiratory stridor	None	Audible with a stethoscope	Audible without a stethoscope			
Retraction	None	Mild	Moderate	Severe		
Air entry	Normal	Decreased	Severely decreased			
Cyanosis	None				With agitation	At rest
Consciousness level	Normal					Altered

6 hours of treatment. The benefit of glucocorticoids is maintained at 12 hours post-treatment but no longer significant after 24 hours.[12] Children treated with glucocorticoids spent less time in the emergency department and were more quickly returned to care, concluding that glucocorticoid use should be not be confined to moderate or severe cases but should be extended to children with mild croup.[11, 12] The small numbers of patients in each study they analysed and the confounding variables made it difficult to make definitive recommendations regarding the superiority of any glucocorticoid, dose, or route of administration.[12] In the absence of further evidence, an oral dose of dexamethasone (0.6 mg/kg) is preferred because of its safety and efficacy. In a child who is vomiting, nebulized budesonide (2 mg) may be considered. Although also efficacious,[8] intramuscular dexamethasone (0.6 mg/kg) cannot be advocated as a first-line treatment given the potential for muscle necrosis with that route of administration. The use of glucocorticoids in primary care in the early management of croup symptoms has transformed the management of this disorder; affected children now rarely require active intervention to support the airway.

Nebulized epinephrine

Nebulized epinephrine (1 mL of 1 in 1000 epinephrine diluted in 3 mL of 0.9% saline) has an established role in the acute paediatric airway in reducing mucosal oedema by an alpha-agonist effect causing vasoconstriction and bronchodilation; a maximum effect is achieved within 30–60 minutes but there is no lasting benefit beyond 2 hours.

The administration of epinephrine does not alter the natural history of the disease but it may postpone or eliminate the need for an artificial airway, or give symptomatic relief until effective treatment can be given.[13] It can be administered at the same time as glucocorticoids.[10, 13] In a recent systematic review evidence did not favour racemic epinephrine versus L-epinephrine or epinephrine delivered by intermittent positive pressure breathing (IPPB) over simple nebulization.[13]

Heliox®

Heliox® is a mixture of helium and oxygen generally supplied with a helium:oxygen ratio of 70:30 or 79:21. Helium is less dense than air or oxygen and is more viscous. Owing to these properties, heliox® is more likely to produce laminar and more efficient flow in the presence of a partially obstructed airway than air or oxygen. Inhaled heliox® delivered through a high-flow system should reduce the work of breathing and result in larger tidal volumes and improved gas exchange. Helium has a high thermal conductivity and so care is needed with humidification in order to avoid hypothermia.[14]

Heliox® has long been used in the management of respiratory conditions and in airway obstruction including croup. There have, however, been few trials examining the benefit of heliox® in the management of children with croup. A recent Cochrane systematic review of the use of heliox® in croup concluded that there was some evidence to suggest a short-term benefit of heliox® in children with moderate to severe croup who have been administered dexamethasone.[15] However, adequately powered randomized controls trials comparing heliox® with standard treatments are required to further assess the role of heliox® in children with moderate to severe croup.

BACTERIAL LARYNGOTRACHEOBRONCHITIS (PSEUDOMEMBRANOUS CROUP, BACTERIAL TRACHEITIS, MEMBRANOUS LARYNGOTRACHEOBRONCHITIS, NEONATAL NECROTIZING TRACHEOBRONCHITIS)

Bacterial tracheitis is a rare but potentially life-threatening cause of upper airway obstruction in children. It is a severe form of laryngotracheobronchitis characterized by the presence of profuse mucopurulent secretions with sloughing of the respiratory epithelium. Secretions are often adherent, are not effectively cleared by coughing and may occlude the airway causing respiratory compromise.[16] Bacterial tracheitis must be differentiated from croup and other causes of infectious upper airway obstruction in order to initiate proper management.

Classically the child with bacterial tracheitis appears toxic with high fevers and worsening stridor that fails to respond to treatment with steroids and nebulized epinephrine. It typically affects children older (mean age 4–8 years) than the usual age group for croup.[17] Like croup, however, it is more common in boys than girls, and there is no single

factor, clinical, radiological or laboratory-based, which reliably distinguishes it from croup.[18] A high level of suspicion is therefore required for early diagnosis. Bacterial tracheitis is a much less common condition than croup.[17] However, there is increased susceptibility in children with Down syndrome or immunodeficiency.[18, 19]

Diagnosis can only be confirmed on airway endoscopy; there is a pseudomembrane in the subglottis and trachea and thick mucopus and debris extending into the bronchi (**Figure 29.2**). Direct laryngotracheobronchoscopy under general anaesthesia and removal of all tracheal secretions, with pulmonary toilet, is mandatory. It is then often necessary to secure the airway by endotracheal intubation for a period of days.[16, 17] The distal airway and the tube itself remain at continued risk of obstruction by secretions, and vigilant expert nursing care is essential. Repeated endoscopic procedures are almost invariably required.

Once the diagnosis is established, broad-spectrum parenteral antibiotics should be commenced immediately. They can later be adjusted in line with the results of microbiological studies. *Staphylococcus aureus* is the pathogen most commonly isolated from tracheal cultures although *Haemophilus influenzae*, *Moraxella catarrhalis*, *Streptococcus pneumoniae* and *Pseudomonas aeruginosa* have also been reported.[16–18] Viral cultures are also frequently positive, indicative that many cases of bacterial tracheitis represent a secondary bacterial infection that follows a viral respiratory tract infection. Most commonly influenza A is identified, although other viruses including the H1N1 strain of influenza A and metapneumovirus have also been isolated.[2, 16, 17, 20]

Complications of this dangerous condition include airway stenosis, acute respiratory distress syndrome, respiratory failure, toxic shock syndrome, anoxic encephalopathy and death.[17]

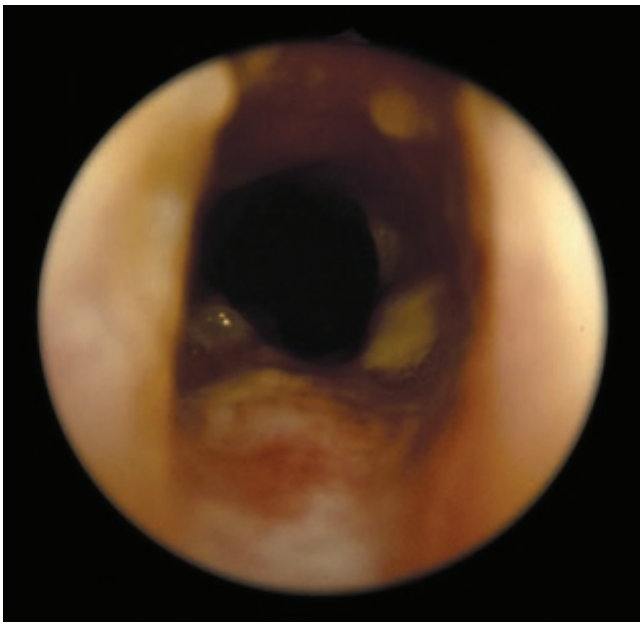

Figure 29.2 Tracheal pseudomembrane in bacterial laryngotracheobronchitis. Image courtesy of Ben Hartley.

Ventilated newborns with an unstable haemodynamic state are at risk of potentially fatal desloughing of the tracheobronchial mucosa. This may be characterized by repeated episodes of acute airway obstruction. Management involves repeated therapeutic tracheobronchoscopy to free the airways.[21]

Recent literature has raised awareness of a less severe clinical presentation which tends to elude diagnosis. There are several reported series of children presenting with a less severe form of bacterial tracheitis who have been effectively managed with antibiotics and endoscopic debridement without the need for endotracheal intubation. The term 'exudative tracheitis' has been proposed as an alternative nomenclature for those with a less severe form and are less systemically ill.[16]

DIPHTHERIA

Diphtheria is rare in countries which have a routine childhood immunization programme, but it continues to present a significant public health problem in the developing world. Diphtheria remains an important differential in the diagnosis of acute laryngeal infection in children, particularly in those who have travelled to endemic areas or have not been vaccinated. Every year there are several reported cases of diphtheria in the UK, primarily in patients who have recently travelled from endemic countries. In 2012, there was a case of fatal diphtheria in a non-immunized child in the UK.[22]

The causative organisms in pathogenic diphtheria are the toxogenic strains of *Corynebacterium diphtheria* and *Corynebacterium ulcerans*. The early clinical picture of upper respiratory tract symptoms is due to the effects of the organism itself. Delayed effects are due to the release of exotoxin.

Symptoms of diphtheria come on gradually and typically begin 2–5 days after exposure. Initial symptoms are of pharyngitis with sore throat and malaise. The child is feverish and on examination there is a typical appearance of the pharyngeal tonsils with necrosis and the development of a characteristic grey pseudomembrane over the surface. This consists of necrotic tissue, bacteria and a rich fibrinous exudate. Early removal causes bleeding but the pseudomembrane may separate more easily later in the course of the disease. There may be a bull-neck appearance due to cellulitis and regional lymphadenopathy.

Diphtheria infection may also involve the larynx. After initial symptoms of dysphagia and toxaemia, symptoms may progress to inspiratory stridor and a barking cough; the cough is frequently paroxysmal and exhausting. Death may follow owing to acute airway obstruction or as a result of the later effects of the exotoxin.[22]

The exotoxin can cause a toxic myocarditis in the second week of the disease and this may be fatal. Peripheral neuritis may also occur, palatal paralysis being the most common effect of peripheral neuropathy and presenting with nasal regurgitation of food and hypernasal speech.

Successful treatment depends on early diagnosis, and the timely administration of high-dose benzylpenicillin and antitoxin (10 000–100 000 units, depending on the severity of infection). Delaying the administration of the antitoxin is associated with increased mortality as the antitoxin does not neutralize toxin that is already bound to tissues. The decision, therefore, to administer antitoxin should be made based on clinical suspicion and should not await microbiological confirmation. Airway management consists of removal of the laryngeal membrane, administration of oxygen and humidification, and endotracheal intubation or tracheostomy if necessary. Systemic steroids may reduce the need for airway intervention.[23] Bed rest is recommended until the danger of myocarditis is past.

ACUTE EPIGLOTTITIS (SUPRAGLOTTITIS)

The classical presentation of acute epiglottitis is well described. It is of a toxic child with a short history of sore throat, inspiratory stridor, muffled voice and drooling due to odynophagia and dysphagia. Left untreated there is progressive respiratory distress. The child is febrile, tachypnoeic and classically will be sitting upright, with the neck extended to optimize the airway, and using the arms to provide support to the shoulder girdle to maximize the efficiency of the accessory muscles of respiration. It is commonest between the ages of 2 and 8 and there is an increased prevalence in winter.[24]

When acute epiglottitis is suspected, pharyngeal examination should not be attempted, as simple manipulation with a tongue depressor may precipitate acute airway obstruction, although the use of a fibreoptic or small rigid endoscope can assist the diagnosis in patients with an atypical presentation.[25] Direct examination of the airway should not be delayed, but should be undertaken in a controlled setting such as an operating room or paediatric intensive care unit by personnel skilled in airway intervention; endoscopic evaluation will confirm gross erythema and oedema of the supraglottic structures (**Figure 29.3**).

When the diagnosis is confirmed, the airway should be secured by endotracheal intubation. If this is unsuccessful, a rigid bronchoscope may be passed to allow tracheostomy. Endotracheal intubation is usually required for safe airway management.[26] Despite this, mortality remains as high as 3%.[27]

Investigations prior to securing the airway are contraindicated, but a soft-tissue lateral radiograph of the neck will typically show a thickened oedematous epiglottis – the 'thumb sign' (**Figure 29.4**). The causative organism can be identified from nasopharyngeal swabs, laryngeal swabs, sputum samples or blood cultures taken after intubation. Traditionally, acute epiglottitis has been a manifestation of invasive Hib infection. This can be confirmed as the cause in partially treated patients by Hib antigen detection in concentrated urine specimens. In the post-vaccination era, epiglottitis is more likely to be caused by 'vaccination breakthough' Hib infection or

Figure 29.3 Acute epiglottitis. Endoscopic appearance. Reproduced by permission of Bruce Benjamin.

Figure 29.4 Acute epiglottitis. Radiological appearance of the oedematous epiglottis (arrowed).

by another pathogen, including meningococci, group A streptococci, pneumococci, *Haemophilus parainfluenzae* and *Staphylococcus aureus*.[14] Immunocompromised individuals are at increased risk of epiglottitis. It may then be due to atypical organisms such as *Herpes simplex* type 1, *Varicella zoster*, *Parainfluenza* or *Candida albicans*.[14] Children with acute epiglottitis should be screened after

recovery from the acute episode to ensure there is no underlying predisposing condition.

Treatment is with intravenous antibiotics; ampicillin resistance due to beta-lactamase production is now over 50% in *Haemophilus influenzae*, so empirical treatment with third-generation cephalosporins for 5–7 days is advised. Chloramphenicol and clindamycin are alternatives in the event of allergy to cephalosporins. Penicillin-sensitive streptococci are the usual cause of acute epiglottitis in children who have been immunized against Hib and they should be treated accordingly. Recovery is characterized by resolution of systemic symptoms and the supraglottic inflammation. The child can then be extubated and discharged from hospital. Since the introduction of Hib immunization, rifampicin prophylaxis has been recommended to eradicate the carrier state for the index case as well as household and school contacts.[28]

Despite the declining incidence of this disease and the changing bacteriology, there has been no change in its clinical presentation over time. It is critically important that reduced clinical experience is not accompanied by a sharp rise in mortality for affected children.

Haemophilus influenzae type b immunization

In addition to acute epiglottitis, other manifestations of invasive *Haemophilus influenzae* infection include meningitis, septic arthritis, septicaemia, pneumonia and osteomyelitis. Serious infections are usually caused by the capsulated forms, serotypes a to f. However, type b was responsible for more than 85% of invasive *Haemophilus influenzae* infection prior to immunization.[15] It has been estimated that, prior to the introduction of immunization, Hib meningitis accounted for 50% of Hib infections, epiglottitis being the next most common presentation.[28]

Routine infant immunization with conjugate Hib vaccine in the UK began in October 1992. Immunization is achieved by three primary doses followed by a late booster. The incidence of invasive Hib infections in children under 5 has fallen dramatically from an incidence of 35.5/100 000 for the year preceding vaccine implementation to 0.06/100 000 in 2012.[29] A reduction in the incidence of acute epiglottitis of approximately 90% has been documented in countries in which an immunization programme has been established. In the UK there was a resurgence of cases in 2003 with over 230 cases of Hib infection, causing a booster programme to be launched.[30] Vaccine failure does occur but in fewer than 10% of cases is there an identifiable clinical risk factor predisposing to infection. An increasing number of cases may be due to infection with an organism other than *Haemophilus* and continued vigilance among clinicians is required.[27] There is evidence that a longer duration of breastfeeding (more than 13 weeks) is associated with a significantly enhanced antibody response to Hib in children aged between 18 months and 6 years.[31]

In the Hib vaccine era, non-type b invasive *Haemophilus influenzae* disease has become more common than type b. It is likely to occur in younger children than is the norm for type b infection, but it is less likely to be meningitis or epiglottitis and more likely to be pneumonia or bacteraemia.[27, 32]

AIRWAY MANAGEMENT

For the child presenting with acute airway obstruction due to laryngeal infection, active intervention to secure the airway may be necessary if symptoms are severe. The options to provide an artificial airway include endotracheal intubation and tracheostomy. Prior to 1975 tracheostomy was the standard intervention, then endotracheal intubation was shown to be a safe alternative for acute epiglottitis and subsequently for croup. Endotracheal intubation is now considered preferable to tracheostomy if circumstances permit. However, the choice of intervention may be influenced by the availability of medical and nursing expertise and local hospital services. The intubated child will require specialized intensive care facilities for management whereas the child with a tracheostomy, while still requiring nursing expertise for optimal management, can be nursed on a normal paediatric ward.

A team approach to management is essential for optimal outcome. The paediatrician, paediatric anaesthetist, paediatric intensivist and paediatric otolaryngologist must collaborate to develop multidisciplinary evidence-based protocols which take into account the availability of local services. Immunization programmes and advances in medical management are changing patterns of disease and have resulted in a decline in the prevalence of acute airway obstruction due to acute epiglottitis, croup and diphtheria; clinicians with little experience of children with these conditions will depend on protocols for safe practice. If endotracheal intubation is to be undertaken, it should be performed in an operating room or paediatric intensive care unit with personnel and equipment available and ready to undertake tracheostomy if the airway cannot be secured.

Once an artificial airway is in place, humidified air should be administered to discourage the development of tenacious secretions. The tube should be aspirated regularly, using suction, to prevent tube obstruction. Nursing vigilance to prevent accidental displacement or self-extubation is essential. In ideal conditions, mortality rates can be as low as 1% for either intervention.[33]

Nasotracheal intubation

Endotracheal intubation for airway obstruction due to acute laryngeal infection is now widely practised with great expertise. When a prolonged period of intubation is anticipated, the nasotracheal rather than the orotracheal route is preferred; nasotracheal intubation is better tolerated so the child requires less sedation, the tube can be secured more reliably and nursing care is easier.

The tube is positioned with the patient anaesthetized and the child is then nursed under sedation, fed via a nasogastric tube. The cough and voice are absent during the period of intubation but after extubation there are normally no sequelae. Complications can occur, however, and include epistaxis at the time of intubation, the development of sinus sepsis during the period of intubation and hoarseness after extubation. The risk of acquired subglottic stenosis is small but is associated with younger age of the child, larger tube size, serial intubation and longer duration of intubation. It is more common in Down syndrome in which there may be an element of congenital subglottic stenosis as a predisposing factor. A tube one size smaller than that usually considered age-appropriate should be used.[34]

Extubation can be considered when the child is systemically well, with minimal tracheal secretions. The 'leak test' (air escape around the nasotracheal tube on application of positive pressure ventilation) is helpful but not an absolute prognostic indicator for successful extubation. In acute epiglottitis, visualization of the epiglottis with a flexible nasendoscope can be useful in monitoring resolution of inflammation. Likewise in laryngotracheobronchitis, whether viral or bacterial, the airway can be monitored using endoscopy until a reduction in tracheal inflammation shows that it is safe to extubate. Systemic steroids administered 6 hours prior to removal of the tube will minimize post-intubation oedema, and nebulized epinephrine can assist with airway patency after extubation.

For acute epiglottitis the period of intubation is usually less than 48 hours but for croup and bacterial laryngotracheobronchitis it may be up to a week.[17] If extubation fails after the acute laryngeal infection has resolved, and despite all the above measures being taken, this may be due to a pre-existing or developing subglottic stenosis. This, if acute and due to mucosal oedema and ulceration, may be successfully treated by a cricoid split (see Vol 3, Chapter 76, Laryngeal stenosis). If not, however, tracheostomy may become necessary and possibly later laryngotracheal reconstruction.

Tracheostomy

Tracheostomy is no longer considered the first choice to secure the airway in acute laryngeal infection. It may be chosen, however, if the availability of nursing expertise and intensive care facilities is limited such that nasotracheal intubation is contraindicated. It may also be necessary if there is severe acute subglottic narrowing precluding the passage of a nasotracheal tube of adequate size for ventilation, or if there has been significant intubation trauma. Equipment and personnel to perform an emergency tracheostomy should always be available in case attempted intubation fails.

Improvements in medical treatments in recent years have seen publications regarding tracheostomy in the management of acute laryngeal infections dwindle from case series to the occasional case report. The largest most recent published series of data on paediatric tracheostomy for croup is from the Red Cross War Memorial Children's Hospital in Cape Town. In that series, 75% of children were decannulated within 10 weeks of formation of the tracheostomy but 54% of children required one or more further procedures after tracheostomy to deal with granulation tissue, supraglottic collapse or subglottic stenosis prior to successful decannulation.[35] Clearly, nasotracheal intubation is preferable if it is possible and practical, depending on local circumstances.

BEST CLINICAL PRACTICE

- ✓ Pharyngeal examination is contraindicated if acute epiglottitis is suspected; it may precipitate acute airway obstruction.
- ✓ Children with croup, whether presenting with mild, moderate or severe symptoms, should be treated with oral dexamethasone at the time of diagnosis. [Grade A]
- ✓ Bacterial tracheitis should be considered in children presenting with croup who fail to respond to treatment with steroids and adrenaline.
- ✓ Nebulized epinephrine (1 mL of 1 in 1000 epinephrine diluted in 3 mL of 0.9% saline) has an established role in the acute paediatric airway. [Grade A]
- ✓ Subglottic stenosis should be remembered in the differential diagnosis of infants presenting with 'recurrent croup'. Consider endoscopy.
- ✓ Equipment and personnel to perform tracheostomy should be immediately available in case attempted intubation is unsuccessful.

FUTURE RESEARCH

- ➤ As Hib vaccination programmes are extended, the incidence of acute epiglottitis should fall even further.
- ➤ Further research is required to determine the optimum dose and route of corticosteroid administration in the treatment of croup.
- ➤ Further studies are required to assess the role of heliox® in the management of children with croup.

KEY POINTS

- The laryngeal airway in children is narrow, especially in the cricoid region. The mucosa is lax and a comparatively minor swelling may cause significant airway compromise.
- Immunization programmes and improvements in medical management have reduced the prevalence of acute laryngeal infection and its severity.
- Systemic steroids have transformed the primary care management of croup. Fewer cases now need hospital admission but vigilance is still required.
- Multidisciplinary evidence-based protocols influenced by the availability of local expertise and services should be formulated and followed to optimize outcomes.
- In acute laryngeal infections, nasotracheal intubation is preferable to tracheotomy if it is possible and practical, depending on local circumstances.

ACKNOWLEDGEMENTS

The author is grateful for the posthumous contribution of Susanna Leighton who wrote the previous edition of this chapter.

CHAPTER 30

CONGENITAL DISORDERS OF THE LARYNX, TRACHEA AND BRONCHI

Chris Jephson

SEARCH STRATEGY

Data in this chapter may be updated by a PubMed search using the following keywords: congenital, anomalies, larynx, trachea and bronchi and focusing on diagnosis and treatment.

INTRODUCTION

The exact incidence of congenital abnormalities of the airway is uncertain, but a figure has been quoted for congenital laryngeal anomalies of between 1:10 000 and 1:50 000 births.[1] Some of these children will have more than one anomaly in the airway.[2]

LARYNX

The larynx is divided into three regions: supraglottis, glottis and subglottis. The supraglottic larynx comprises the epiglottis, aryepiglottic folds, false cords and ventricles. The glottis consists of the vocal cords (also referred to as vocal folds). In children, the subglottis extends from the under surface of the vocal cords to the inferior border of the cricoid cartilage.

Supraglottis

Laryngomalacia

Laryngomalacia is characterized by partial or complete collapse of the supraglottic structures on inspiration and is the most common congenital cause of stridor.[3] The pathophysiology is thought to be related to the characteristic anatomical abnormalities that are observed: the epiglottis is long and curled (omega-shaped); the aryepiglottic folds are short and tightly tethered to the epiglottis; there may also be redundant mucosa and submucosa of the aryepiglottic folds medially. The result is a tall, narrow supraglottis with a deep interarytenoid cleft where the epiglottis is soft and may curl and collapse and the mucosa may prolapse into the airway (Figure 30.1). It has been suggested that there may also be an element of neuromuscular immaturity and consequent incoordination of arytenoid movements.

The rather characteristic high-pitched, fluttering inspiratory stridor is usually present at, or shortly after, birth. It is very variable, typically being most noticeable when the infant is active or upset, and may disappear when the child is asleep. The severity of the stridor tends to increase as the child becomes more active during the first 9 months of life, and then gradually diminishes until by the age of 2 years it has generally disappeared. Very rarely, stridor may persist into late childhood.

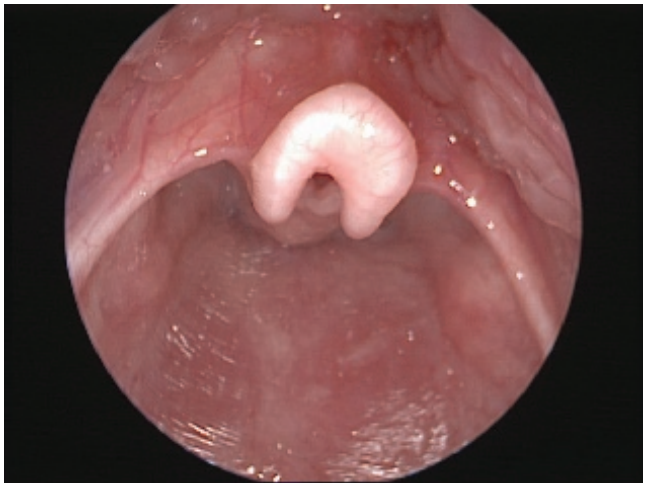

Figure 30.1 Laryngomalacia.

The diagnosis can be confirmed in the outpatient setting by flexible fibre-optic laryngoscopy. Nasendoscopy is usually possible in children up to the age of 1 year. The child should be wrapped in a blanket and held firmly by a nurse or parent. The supraglottic collapse on inspiration, which is typical of laryngomalacia, is easily seen. In approximately 90% of reported cases the condition is mild, no intervention is needed and the parents can be reassured accordingly.[4] In these cases a period of observation should be undertaken with documented regular weights to demonstrate no failure to thrive. A 4-week course of antireflux medication can be prescribed for those children with regurgitation and gastro-oesophageal reflux disease (GORD).

In severe laryngomalacia, however, there is serious respiratory obstruction with substantial sternal and intercostal recession together with feeding difficulties which may be compounded by reflux enhanced by the high negative intrathoracic pressures generated, and consequent failure to thrive. Matters are made worse if there are other factors increasing the level of cardiorespiratory embarrassment, such as congenital cyanotic heart disease. In the most severe cases, cor pulmonale may ensue and in cases of severe sternal recession a permanent pectus excavatum may develop. Therefore, in children where the stridor is severe, if there is failure to thrive or there are any atypical features (e.g. history of previous intubation, cutaneous haemangioma) that may raise the suspicion of a second, coexisting airway pathology, a microlaryngoscopy and bronchoscopy (MLB) under general anaesthesia is indicated. Optimum conditions for diagnosis require the child to be breathing spontaneously under a very light level of anaesthesia, with the beak of the laryngoscope in the vallecula; the supraglottic collapse is not seen under deep anaesthesia and will be prevented if the tip of the laryngoscope is introduced into the laryngeal vestibule.

Children who show signs of failure to thrive should undergo an endoscopic aryepiglottoplasty (sometimes termed a supraglottoplasty).[5] In this procedure, the larynx is visualized using a laryngoscope in suspension, with its beak positioned in the vallecula. Using cup forceps and microscissors, each aryepiglottic fold is first divided to release it from the edge of the epiglottis, and any redundant mucosa and submucosal tissue are then excised from over the arytenoids, together, if necessary, with part or all of the cuneiform cartilages. In less severe cases it may only be necessary to incise the tight aryepiglottic fold.[6] The 'bridge' of mucosa between the arytenoids is carefully preserved to prevent interarytenoid scarring. Bleeding is minimal and is easily stopped by the application of neurosurgical patties dipped in topical adrenaline (1:10 000). Neither antibiotics nor steroids are routinely given, complications are very rare, and the stridor is usually improved immediately following the surgery. In cases where the stridor and feeding difficulties persist, an underlying hypotonic neurological disorder is likely.[7]

Saccular cysts and laryngocoeles

Laryngeal cysts are rare, can be congenital or acquired and may present with respiratory obstruction in infants and young children (**Figure 30.2a**). They are divided into laryngocoeles and saccular cysts. The ventricle is the fossa bounded by the false vocal fold and the vocal cord. The anterior portion of the ventricle leads superiorly to the saccule. A laryngocoele is an air-filled dilatation of the laryngeal ventricle which communicates with the laryngeal lumen. It is an uncommon lesion which usually occurs in middle age but may rarely be seen in infancy, when it can produce respiratory distress which typically becomes worse on crying due to increased distension of the laryngocoele with air. However, a laryngocoele may obstruct and fill with mucus or become infected (laryngopyocoele), thus becoming indistinguishable from a saccular cyst.

A saccular cyst also represents an abnormal dilatation or herniation of the saccule of the ventricle of the larynx; however, it differs from a laryngocoele in that there is no opening into the larynx and it is filled with mucus instead of air. It is considered to form as the result of a developmental failure to maintain patency of the orifice between the saccule and the ventricle, and may be of anterior or lateral type. The anterior saccular cyst extends medially

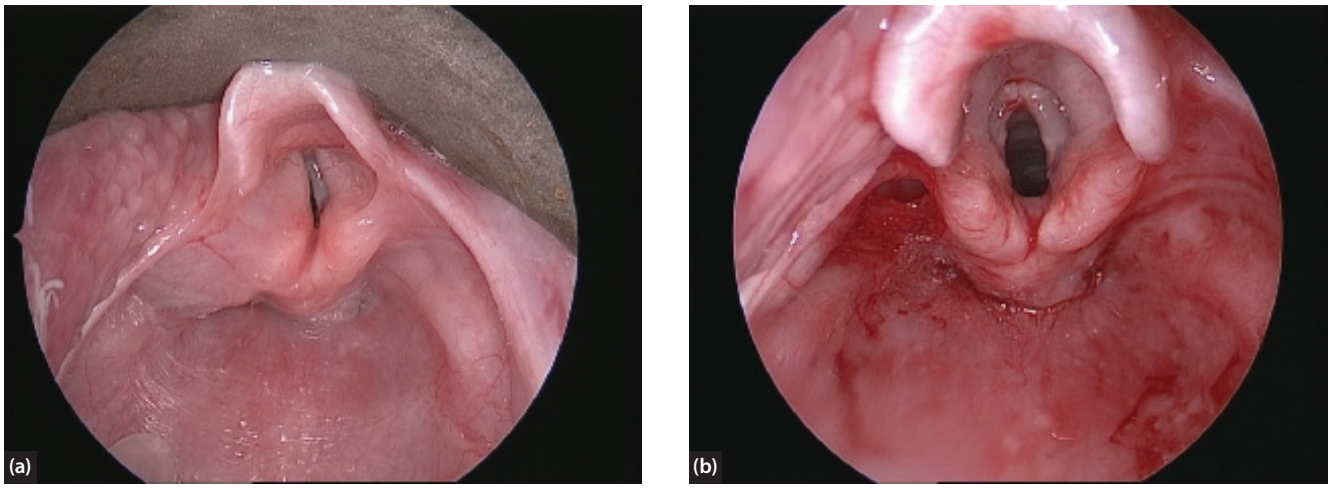

Figure 30.2 Left saccular cyst, showing **(a)** obstruction of the laryngeal inlet, and **(b)** post marsupialization.

and posteriorly from the saccule and so protrudes into the laryngeal airway between the true and false vocal cords. The lateral saccular cyst is most common in infants and expands posterosuperiorly into the false cord and aryepiglottic fold.[8]

Laryngeal cysts are classified as internal or type 1 if contained entirely within the laryngeal framework, and external or type 2 if it pierces the thyrohyoid membrane.[9] Diagnosis is confirmed by endoscopy, except in an external laryngocoele where no abnormality may be seen except on imaging. Saccular cysts are best treated at the initial endoscopy by wide endoscopic marsupialization (**Figure 30.2b**). If the cyst recurs, then the procedure of choice is a lateral cervical approach extending through the thyrohyoid membrane at the superior margin of the ala of the thyroid cartilage, with subperichondrial resection of a portion of the upper part of the ala. Through this 'window' the cyst can be completely excised, using short-term intubation to secure the airway post-operatively.

Vascular malformations

Vascular malformations include lymphatic malformations, venous malformations and arteriovenous malformations and are discussed in detail in other chapters. Vascular malformations are rare in the larynx, trachea and bronchi. Lymphatic malformations (also termed lymphagiomas or cystic hygromas) are cystic malformations that result from abnormal development of the lymphatic vessels. In the head and neck they may be macrocystic (usually infrahyoid), microcystic (usually suprahyoid) or a combination of the two. Occasionally, a microcystic lymphatic malformation may extend into the tongue base, valleculae and supraglottis, and airway obstruction may result. If the lymphatic malformation is very extensive, a tracheostomy may be required, but where supraglottic involvement is less severe it may be possible to debulk the lesion by endoscopic vaporization using a CO_2 laser or radiofrequency ablation.[10, 11]

Bifid epiglottis

Bifid epiglottis is a rare laryngeal anomaly in which the epiglottis fails to fuse in the midline and thus has a cleft extending down to its tubercle. It may be seen as a feature of Pallister–Hall syndrome, the cardinal elements of which are hypothalamic hamartoblastoma, hypopituitarism, imperforate anus and postaxial polydactyly. It usually presents with feeding difficulties due to aspiration and with stridor because of collapse and enfolding of the two halves of the epiglottis. Endoscopy establishes the diagnosis, and treatment options include amputation of the epiglottis and tracheostomy.

Glottis

Laryngeal webs

Failure of complete canalization of the larynx during embryogenesis may result in a glottic or, very rarely, a supraglottic web. The majority involve the anterior glottis, fusing

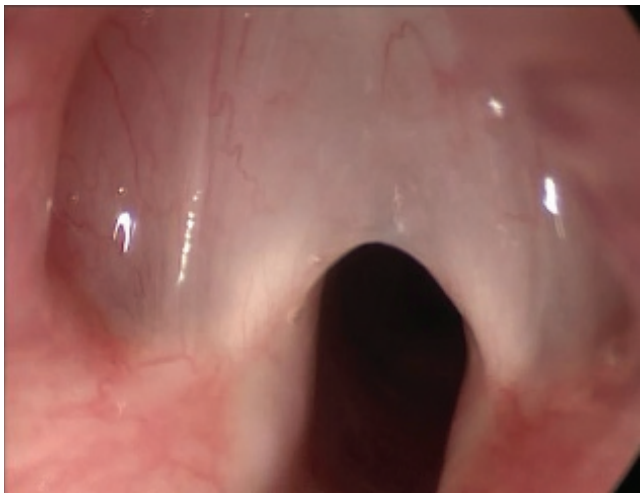

Figure 30.3 Anterior glottic web.

the vocal cords along a variable part of their length, and producing a correspondingly variable degree of respiratory obstruction and dysphonia (**Figure 30.3**). Characteristically there is inspiratory stridor and a rather weak, high-pitched, squeaky voice. The combination of a weak cry from birth and recurrent croup in infancy should always raise suspicion of a laryngeal web. Anterior laryngeal web can also be associated with 22q11 deletions, other chromosomal anomalies and cardiac abnormalities.[12] Occasionally, a congenital posterior, interarytenoid web occurs and may be associated with cricoarytenoid joint fixation.

Almost all anterior glottic webs are fairly thin posteriorly, close to their free border, but become progressively thicker anteriorly with increasing subglottic extension. Where the web is small and causing little in the way of symptoms it is usually best to treat conservatively. A longer isolated web with little or no subglottic involvement may be divided endoscopically along the margin of one vocal cord with a knife or CO_2 laser; if it is very thin, subsequent endoscopic dilatation may be sufficient to permit stable healing without the web reforming. However, most glottic webs are quite thick anteriorly and extend to varying degrees into the subglottis. A keel placed endoscopically following division can prevent recurrence. In the young child with a small larynx a covering tracheostomy is necessary for the 2 weeks that the keel is in place. In cases where the airway is very small and there is associated subglottic stenosis a laryngotracheal reconstruction (LTR) with anterior cartilage grafting is required. This can be carried out in the infant as a single-stage procedure with post-operative endotracheal intubation to stent the larynx for 5–7 days. However, in practice, most infants with a severe glottic web will have a tracheostomy performed in which case the LTR can be deferred to the age of about 1–2 years, when the larynx is larger and the vocal cord dissection can be undertaken more precisely.

Laryngeal atresia

Laryngeal atresia is incompatible with life unless there is an associated tracheo-oesophageal fistula (TOF) which

permits ventilation via a tube in the oesophagus, or unless an emergency tracheostomy is performed in the delivery room. However, there are now cases being recognized antenatally on ultrasound imaging and managed with an *ex utero* intrapartum treatment (EXIT) procedure, whereby a tracheostomy is undertaken following elective Caesarean section with the neonate still on placental circulation.[13]

Cri-du-chat syndrome

This syndrome is primarily characterized by a cat-like mewing cry in infancy, microcephaly, downward-slanting palpebral fissures, mental retardation and hypotonia. It is caused by chromosome 5p deletion. At endoscopy, observation during phonation reveals that the posterior part of the glottis remains open, giving it a diamond-shaped appearance.[14] There is no respiratory embarrassment and the cry becomes less abnormal as the child grows older.

Vocal cord paralysis

Vocal cord paralysis is the second most common congenital anomaly of the larynx after laryngomalacia. Up to 45% of patients may have other, coexisting airway pathology and so, although outpatient flexible fibre-optic laryngoscopy may indicate the diagnosis, a formal MLB under general anaesthesia is essential. Laryngeal ultrasound can be an accurate and reproducible method of assessing vocal cord movement, and it may be useful in monitoring a child with known vocal cord palsy and in the diagnosis of the very sick child who may be unfit for endoscopy under general anaesthesia.[15] Approximately half of cases are unilateral and half bilateral.

Unilateral vocal cord paralysis is usually not congenital, most cases being acquired as a result of surgical injury to the left recurrent laryngeal nerve, often following correction of a congenital cardiac anomaly. Patients present with mild stridor, dysphonia and sometimes aspiration. If the vocal cord lies in an intermediate position, surgical intervention is not usually necessary, and the voice can be expected to improve as time passes and either recovery occurs or the other vocal cord compensates. If the vocal cord lies in a more abducted position, the dysphonia may be more pronounced and aspiration more likely. Vocal cord medialization procedures such as thyroplasty and augmentation injection can improve the dysphonia and aspiration, but these may result in worsening of the stridor.

In contrast, bilateral vocal cord palsy is usually a congenital abductor paralysis. The vocal cords lie in the paramedian position with consequent inspiratory stridor, and a tracheostomy is necessary in approximately half of cases, most of which have other associated airway pathology. A classical cause of congenital bilateral vocal cord palsy is hydrocephalus with the Arnold-Chiari malformation. Once the diagnosis is made, prompt correction of the raised intracranial pressure with a shunt often improves vocal cord movement and a tracheostomy may thus be avoided. However, most cases of congenital bilateral vocal cord paralysis are idiopathic and the approach to management is greatly influenced by the fact that up to 58% will eventually recover, with 10% taking more than 5 years to do so and one reported case of recovery at the age of 11 years.[16] This strongly suggests that the problem is often one of delayed maturation in the vagal nuclei and argues convincingly in favour of a conservative management philosophy. Furthermore, where the airway is marginal, it may become adequate with laryngeal growth alone, and glottic enlargement surgery in order to avoid a tracheostomy or achieve decannulation may improve the airway at the expense of the voice.

The infant with an inadequate airway and failure to thrive will require a tracheostomy. If vocal cord movement does not develop and the airway does not become adequate as a result of laryngeal growth, then an endoscopic laser cordotomy or arytenoidectomy should be considered at the age of 11 or over, following a full discussion with the child and parents regarding the possible trade-off between airway and voice. If it is considered imperative to achieve decannulation earlier, perhaps because of poor social circumstances, an endoscopic laser cordotomy can be attempted as early as 2 years of age. If that fails, an external arytenoidectomy via a laryngofissure may be carried out at the age of 4–5 years with the prospect of an 84% decannulation rate;[17] however, there is a small risk of aspiration as well as loss of voice quality and the procedure is irreversible.

Subglottis

Congenital subglottic stenosis

Congenital subglottic stenosis is due to defective canalization of the cricoid cartilage and/or conus elasticus, resulting in either gross thickening of the anterior lamina of the abnormal cricoid (**Figure 30.4**)[18] or a small, elliptical, thickened cricoid with excessive submucosal soft tissue (**Figure 30.5**).[19] Alternatively, there may be anterior fusion of the vocal cords, forming a web with subglottic extension, as seen in 22q11 deletion syndromes. Subglottic stenosis is said to be the third most common congenital anomaly of the larynx, but its true incidence is hard to determine because many patients are intubated in the neonatal period and are then considered by definition to have an acquired stenosis. The reality in this situation may be a combined congenital plus acquired stenosis. Milder degrees of stenosis present as inspiratory or biphasic stridor as the child becomes older and more active, or as recurrent ‘croup’ owing to superimposed oedema from upper respiratory tract infections.

Diagnosis requires an MLB. The exact location of the stenosis with respect to the vocal cords, tracheostome and carina is measured and the number of normal tracheal rings above the tracheostome is counted. Passing endotracheal tubes and sizing the stricture measures the degree of stenosis. The Myer-Cotton grading system is widely used

Figure 30.4 Congenital subglottic stenosis, showing anterior cricoid thickening. Reused with kind permission from C.M. Bailey and Springer Science and Business Media.[18]

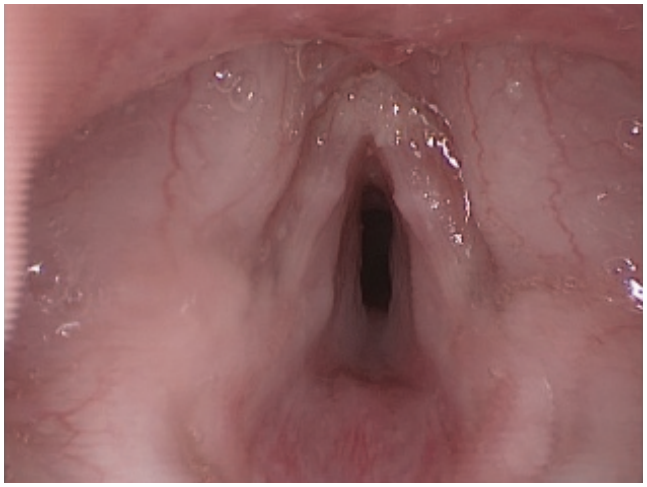

Figure 30.5 Congenital subglottic stenosis, showing elliptical, thickened cricoid with excessive submucosal soft tissue.

to classify paediatric laryngotracheal stenosis into four grades of severity:[20]

- **Grade I :** 0–50% obstruction
- **Grade II:** 51–70% obstruction
- **Grade III:** 71–99% obstruction
- **Grade IV:** 100% obstruction.

This helps to predict the outcome of surgical reconstruction.

If the airway is not severely compromised, surgery may not be required, especially as a congenital stenosis can be expected to enlarge with growth. Congenital cartilaginous stenosis represents a strict contraindication to dilatation or laser resection: any type of endoscopic treatment is liable to worsen the initial condition, and attempted dilatation is inevitably ineffective as the thickened ring of cricoid cartilage cannot be expanded.

If the airway is severely compromised, a tracheostomy is needed. This can sometimes be avoided in specialist centres where there are facilities for single-stage airway reconstruction in which an endotracheal tube is used as a stent, usually for a period of 5–7 days.

The surgical options have evolved from the classical castellated laryngotracheoplasty designed by Evans and Todd[21] in the early 1970s to achieve laryngeal framework expansion. This was superseded during the early 1980s by the LTR, devised primarily by Cotton.[22] The LTR involves augmentation of the laryngotracheal complex by anterior and/or posterior midline incision of the cricoid with insertion of costal cartilage grafts to expand the airway. This technique has now been supplemented by the partial cricotracheal resection (PCTR), which was introduced into the paediatric age group by Monnier et al.[23] in the early 1990s. This involves complete resection of the stenotic segment with end-to-end anastomosis of the tracheal stump to the thyroid cartilage.

Grade I subglottic stenosis usually requires no surgical intervention. Grade II stenosis can be reconstructed by means of an LTR with anterior cartilage grafting +/– posterior cricoid split. Mild grade III stenosis is likely to need an anterior graft with posterior cricoid split +/– posterior cartilage grafting. Severe grade III stenosis (a pinhole airway) requires both anterior and posterior grafts. Grade IV stenosis demands anterior and posterior grafts with prolonged stenting. For severe grade III and for grade IV stenosis, PCTR is an alternative technique with much to commend it. LTR remains the last surgical option after failed PCTR if it is impossible to resect a further segment of trachea.

In cases of congenital subglottic stenosis, the LTR may be combined with submucosal resection of cartilage to 'core out' the thickened anterior cricoid ring. A similar submucous resection technique can be used via a laryngofissure for thick anterior glottic webs with subglottic extension. In both situations stenting is essential.

The least severe grades (I and II) have a better outcome than the most severe grades (III and IV). For PCTR, however, the grading system is not a predictor of success or failure, because the stenotic segment is completely resected. Results from the most experienced centres[24, 25] show a success rate of over 90% for grades I and II subglottic stenosis following LTR and approximately 80–90% for grades III and IV subglottic stenosis. The latest results from the two centres with the largest experience in PCTR show a decannulation rate of 98% for primary surgery and 94% for salvage surgery after failed previous airway reconstruction.[26, 27]

For more detail on the management of laryngeal stenosis, see Chapter 31, Acquired laryngeal stenosis.

Subglottic haemangioma

Infantile subglottic haemangioma is a well-recognized cause of gradually worsening inspiratory or biphasic stridor presenting in the first few weeks of life, with 85% presenting within the first 6 months. Of patients with a cutaneous haemangioma 1–2% also have a subglottic lesion; 50% of patients with a subglottic haemangioma will have a coexisting cutaneous lesion. The natural history is typically a proliferative phase lasting 6–12 months followed by complete involution over 1–5 years.[28]

At endoscopy the typical appearance is of a compressible, pear-shaped red swelling in the subglottis on one side, left more commonly than right (**Figure 30.6**). Larger haemangiomas may be circumferential and, uncommonly, may extend down into the trachea or through its wall into the surrounding soft tissues of the neck or mediastinum. The appearance is so characteristic that biopsy is unnecessary; in rare cases where there is doubt, biopsy can be undertaken without fear of troublesome bleeding because the lesion is a benign endothelial cell tumour, not a vascular malformation. If extension outside the airway is suspected, magnetic resonance imaging (MRI) is indicated. Subglottic haemangioma is life-threatening because of its situation in the narrowest part of the airway and therefore requires rapid intervention.

Tracheostomy will maintain the airway until involution occurs. A review of the subject in 1984 by Sebastian and Kleinsasser[29] estimated that 50–70% of patients with airway haemangioma require a tracheostomy, and that children managed with tracheostomy alone could be decannulated at a mean age of 17 months. However, paediatric tracheostomy carries a mortality of 1–2% and a significant morbidity including delayed speech development.

Over the years, efforts have been made to develop alternative therapeutic strategies aimed at maintaining the airway without recourse to tracheostomy. Therapies used in the past include radiotherapy, CO_2 laser ablation, systemic steroids, intralesional steroid injection followed by intubation, and interferon alpha-2a. However, all of these are associated with unwanted side effects. Submucosal surgical excision of subglottic haemangioma was first described in 1949.[30] Surgery is carried out in a single stage and is stented with an endotracheal tube for 3–5 days. Surgical excision is unsuitable if the haemangioma is circumferential or extends onto the vocal cords.

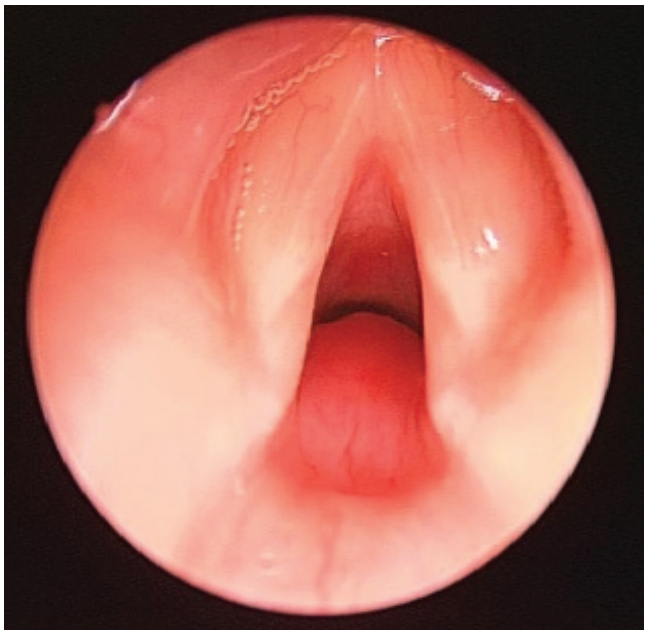

Figure 30.6 Subglottic haemangioma.

The treatment of subglottic haemangiomas was revolutionized with the incidental finding that propranolol is an effective treatment for cutaneous haemangioma and subglottic haemangioma.[31,32] Prior to treatment commencing, a baseline pulse, blood pressure and blood glucose should be assessed together with an ECG and echocardiogram. Treatment is initiated at 1 mg/kg/day for 1 week, then advancing to 2–3 mg/kg/day as tolerated.[33] Propranolol has proven to be effective at reducing/resolving stridor in as little as 24 hours. Side effects of propranolol are rare but may include hypoglycaemia, hypotension and bradycardia. Treatment should be for a minimum 12 months to cover the natural period of proliferation, then weaning of the propranolol dose over 4 weeks. These patients should be closely monitored for recurrence.

Propranolol is now considered to be first-line treatment for subglottic haemangiomas. Steroid therapy can be used in the acute setting and in conjunction with propranolol for unresponsive lesions. Submucous resection remains a valid alternative for non-circumferential haemangiomas and those not involving the vocal cords.

Laryngeal and laryngotracheo-oesophageal cleft

Posterior laryngeal clefts result from failure of the posterior cricoid lamina to fuse, and in the more extensive laryngotracheo-oesophageal clefts there is also incomplete development of the tracheo-oesophageal septum. The classification devised by Benjamin and Inglis[34] has been widely adopted because it relates well to symptoms and treatment. A type I cleft extends down to the level of the vocal cords; a type II cleft extends below the vocal cords into the cricoid (**Figure 30.7**); a type III cleft extends down into the cervical trachea; and the, fortunately rare, type IV cleft extends into the thoracic trachea and may even reach the carina. Approximately 25% of patients with a laryngeal cleft will also have a TOF, but conversely the incidence of laryngeal cleft in patients with a TOF is low. Abnormalities of the tracheal ring structure in cleft patients may result in associated tracheomalacia, which can add to the difficulties of management.

The majority of laryngeal cleft patients have associated congenital abnormalities, of which TOF is the most common. These may include tracheobronchomalacia, congenital heart disease, dextrocardia and situs inversus. Often there is severe gastro-oesophageal reflux. Laryngeal clefts are characteristic of two syndromes: the Opitz-Frias syndrome (G syndrome) comprising hypertelorism, cleft lip and palate, laryngeal cleft and

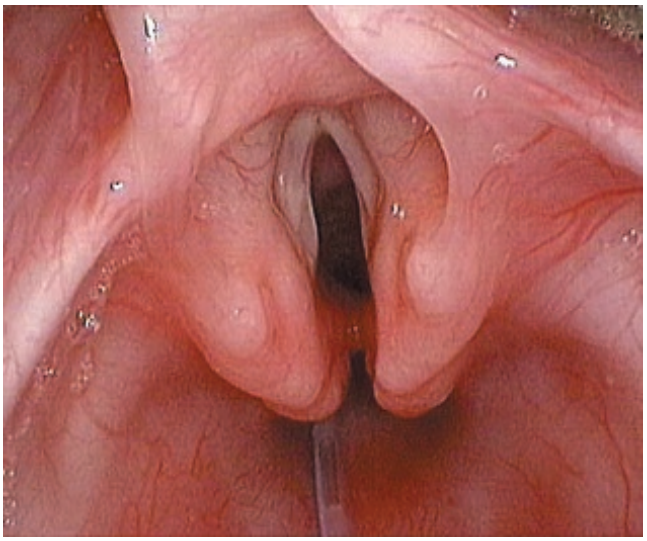

Figure 30.7 Larnygeal cleft (type II). Reused with kind permission from C.M. Bailey and Springer Science and Business Media.[18]

hypospadias; Pallister–Hall syndrome (described earlier in relation to bifid epiglottis), consisting of congenital hypothalamic hamartoblastoma, hypopituitarism, imperforate anus and postaxial polydactyly, and sometimes including a laryngeal cleft.

As might be expected, symptoms become more severe the longer the cleft. Type I clefts present with cyanotic attacks on feeding and recurrent chest infections. Stridor (similar to that of laryngomalacia) may be a feature, secondary to prolapse of the cleft edges into the airway. The differential diagnosis for infants presenting with these symptoms includes gastro-oesophageal reflux, neuromuscular incoordination of deglutition, vocal cord paralysis, raised intracranial pressure and TOF. Type II and III clefts produce dramatic aspiration with recurrent pneumonia, sometimes with stridor and an abnormal cry. Type IV clefts cause severe aspiration, cyanosis and incipient cardiorespiratory failure.

Investigation of the child with aspiration and stridor requires a careful MLB; no other diagnostic method can replace it.[35] Suspension microlaryngoscopy allows the use of two probes to part the arytenoids, and without this manoeuvre the diagnosis may be missed as redundant mucosa tends to prolapse into the defect and obscure it. A plain chest X-ray may show changes secondary to recurrent aspiration pneumonitis. A lateral neck X-ray may demonstrate vaguely increased laryngeal soft tissue and the nasogastric feeding tube may be seen protruding anteriorly into the airway. Videofluoroscopic contrast swallow studies may not differentiate laryngeal incompetence from neuromuscular incoordination, and a high index of suspicion is required.

The approach to treatment depends entirely upon the length of the cleft. A short type I cleft with no aspiration requires no treatment. Minimal aspiration may be managed by thickening the feeds. Significant aspiration requires endoscopic repair of the cleft in two layers, using a nasogastric feeding tube until the suture line has healed. A very short type II cleft may also be repaired endoscopically, albeit with difficulty, using a nasogastric tube. However, a long type II or a type III cleft needs to be approached anteriorly through an extended laryngofissure with a low tracheostomy to cover the procedure; a nasogastric tube will tend to erode through the suture line, and so a gastrostomy is required (usually combined with a Nissen fundoplication to control reflux reliably). These children take many months to learn to swallow after successful cleft repair and thus long-term gastrostomy feeding is necessary. Surgical repair of the cleft is undertaken in three layers in an effort to optimize healing: the two mucosal layers are reinforced by an interposition graft of tibial periosteum or temporalis facia.

The type IV cleft presents an altogether more difficult surgical challenge. Owing to the length of the cleft, a tracheostomy is unhelpful in stabilizing the airway, and the convexity of the tube would tend to erode through the party wall suture line; the repair must therefore be undertaken using a single-stage technique with endotracheal extubation taking place 7–10 days post-operatively. Short type IV clefts may be managed by an anterior approach through a cervical incision, if necessary pulling the trachea up into the neck to reach the lower end of the cleft. Longer clefts will require a lateral cervical approach in combination with a thoracotomy, or preferably an anterior cervicothoracic approach via a median sternotomy with repair on extracorporeal membrane oxygenation (ECMO) or cardiopulmonary bypass. Post-operatively, tracheomalacia may prevent extubation and so a tracheostomy may be needed once the cleft has healed soundly.[36]

Mortality remains significant, being approximately 14% overall,[37] rising to 66% for type IV laryngotracheo-oesophageal clefts and up to 100% for full-length clefts ending at the carina.[38] A large proportion of the mortality is from causes unrelated to the cleft, and notable morbidity is produced by other associated congenital abnormalities and often by delay in reaching the correct diagnosis. Management should be in a major paediatric centre where a full multidisciplinary team is available with full neonatal and paediatric intensive care facilities.

TRACHEA AND BRONCHI

Advances in the field of airway regenerative medicine mean that tissue engineering is becoming a realistic potential therapy for congenital tracheal and bronchial malformations.[39] Initial research focused on engineering biocompatible and immunocompatible material to act as a scaffold to directly repair any defect, with the aim that the scaffold would become populated by the patient's own, normal-functioning cells – in particular, ciliated respiratory epithelium. Crucially in neonates and children, the scaffold needs to be able to grow with the child. Successful tracheal transplantation has occurred in paediatric patients using decellularized donated cadaveric trachea.[40, 41] The search for the perfect scaffold material, whether natural or synthetic, is ongoing.

Agenesis

Tracheal agenesis may be complete (full-length) or partial, but in either case there is no continuity between the larynx and the bronchi. Occasionally, short-term survival may be possible if there is a broncho-oesophageal fistula, which can permit some airflow into the lungs, but surgical efforts to use the oesophagus as a tracheal replacement have not been successful and long-term survival has not proved possible. The majority of cases are complicated by other severe congenital abnormalities.

Agenesis of one main bronchus and its associated lung is not as rare as tracheal agenesis and is compatible with survival, although such children often have coexisting congenital anomalies and are at risk from chest infections because of their much-reduced respiratory reserve. Bilateral bronchial and pulmonary agenesis is extremely rare and is, of course, fatal. Occasionally, localized atresia occurs in a peripheral bronchus, resulting in a distal mucocoele which may need to be resected if it is causing severe compression of the surrounding lung.

Stenosis

Occasionally, a membranous web may be encountered in the trachea with a normal underlying cartilaginous ring structure. Such cases usually fare well with endoscopic rupture and dilatation. Thicker congenital fibrous stenoses may be amenable to radial KTP laser incision and balloon dilatation, followed by application of mitomycin C to reduce the risk of restenosis[42] or tracheal resection with end-to-end anastomosis. A short stenosis may also be associated with one or two absent tracheal rings, although the most common finding in congenital tracheal stenosis (CTS) is a segment of complete tracheal cartilaginous rings with an airway lumen as narrow as 2 mm.[43]

CTS is usually described as being either short-segment or long-segment and according to whether it involves trachea alone, trachea and bronchus, or bronchus alone. A long-segment congenital tracheal stenosis (LSCTS) is one that is over 1 cm in neonates and 1.5 cm in infants or greater than 50% of the length in older children. Further classification depends on the associated anatomy of the respiratory tract: normal bifurcation, bronchial trifurcation, porcine bronchus or single lung.[44] Sixty per cent of patients with LSCTS will have associated malformations such as pulmonary artery sling, right-sided aortic arch, subglottic stenosis and tracheoesophageal fistula.

Children with congenital tracheal stenosis usually present with respiratory distress within the first year of life. Symptoms usually only appear when there is greater than 50% stenosis. Symptoms may become apparent in the neonatal period with biphasic stridor, respiratory distress, tracheal tug and episodes of cyanosis. However, presentation may be delayed until the infant is several months old when greater physical activity makes increasing demands upon the respiratory system. In addition, difficulty in breathing can develop rapidly as a result of a respiratory tract infection, with consequent oedema and increased secretions. In this situation the child may require endotracheal intubation, and it is then found that only a very small-sized tube can be passed. In the case of a long, tapering stenosis, which may narrow virtually to a pinhole, this is a dangerous situation. The tube tip tends to impact into the stenosis, granulations begin to develop and obstruct the already perilous airway, and endoscopic evaluation is then a procedure fraught with difficulty. In such cases the stenosis often seems surprisingly severe considering the child's mild symptoms prior to the precipitating illness.

Suspected LSCTS should be assessed and managed by a multidisciplinary team including cardiothoracics, ENT surgeons, upper GI surgeons, respiratory and cardiac paediatricians, interventional radiologists and allied healthcare professionals. Investigations should be targeted at identifying the extent of the abnormality.

Endoscopy remains the 'gold standard' investigation for a child with stridor. MLB demonstrates complete tracheal rings without the posterior bulge of trachealis (**Figure 30.8**). However, if LSCTS is found at MLB, great care must be taken not to traumatize the stenosis by attempting to pass an endoscope that is too large or the resultant oedema may convert an airway that is just adequate into one that is not. Frequently, the stenosis is too narrow to permit passage of the 4 mm rigid telescope or the smallest (size 2.5) bronchoscope, and it is necessary to use the unsheathed 1.9 mm telescope to survey the length of the narrow segment and assess the state of the distal trachea, carina and bronchi. Sometimes the airway is too narrow to admit even this extra-slim telescope, and then the surgeon must rely on contrast bronchography.

Bronchoscopy and bronchography (B&B) demonstrate the the size of the tracheal lumen and outline the trachea and bronchi distal to the stenosis, which may be too narrow to permit passage of a bronchoscope (**Figure 30.9**) and also provides a dynamic assessment of any malacic segments. Optical coherence tomography (OCT) can be combined with B&B to confirm the presence of complete rings if there is any doubt. Contrast CT and an echocardiogram are essential in view of the high incidence of associated anomalies of the heart and great vessels. CT is particularly helpful in assessing the vascular anatomy and its relationship to the trachea and 3D reconstructions allow better surgical planning.

Figure 30.8 Complete tracheal rings.

Figure 30.9 Tracheal stenosis: bronchogram of a long-segment lower tracheal stenosis with associated stenosis of the main bronchi and with a 'pig' bronchus at its upper end.

Mild cases with minimal symptoms may require no intervention after the diagnostic endoscopy, as the trachea can grow and there may be only slight limitation of exercise tolerance. Very narrow, short segments can be excised with end-to-end anastomosis. In the past, several techniques have been employed to treat LSCTS. Augmentation tracheoplasty with costal cartilage grafting or a pericardial flap or free patch have been described. However, if the stenosis is severe with only a pinhole lumen, cartilage grafting cannot be expected to achieve an adequate airway, and a large suspended pericardial patch carries high risk of subsequent tracheomalacia. The overall mortality associated with costal cartilage or pericardial patch tracheoplasty is substantial, ranging up to nearly 50%.[45]

Successful endoscopic balloon dilatation of LSCTS has been reported. However, it is difficult to see why the airway does not quickly close down again to its original size, as the 'spring' in the cartilage is not broken by splitting it in just one place and fibrosis is bound to occur at the site of the split. For this reason, balloon dilatation is used as an adjunctive treatment modality for granulations and fibrous stenoses such as may develop post-operatively at the site of an anastomosis.

For LSCTS, the gold standard treatment of choice is slide tracheoplasty with the patient on cardiopulmonary bypass with concurrent repair of coexisting cardiovascular anomalies. The slide minimizes shortening of the trachea and hence reduces anastomotic tension. The oblique anastomosis also seems less liable to post-operative stenosis than an end-to-end anastomosis. The tracheoplasty is performed by dividing the stenosis at its midpoint, incising the proximal and distal narrowed segments vertically on opposite anterior and posterior surfaces and sliding these together. The stenotic segment is thus shortened by half, the circumference is doubled, and the luminal cross section quadrupled. Long resections may require a laryngeal drop and/or hilar release to avoid undue tension upon the suture line.

Survival rates for LSCTS following slide tracheoplasty over the last decade have risen to nearly 90%.[44] Poor prognostic indicators include pre-operative bronchomalacia and bronchial stenosis, although these groups still have survival rates of over 70%. Balloon dilatation is used to treat granulations and stenosis. Absorbable PDS stents offer an advantage over metallic stents and are used to treat malacia, particularly bronchomalacia.

Slide tracheoplasty has proven to be very successful in treating LSCTS. However, for those children who have failed surgery or in cases not amenable to slide tracheoplasty, few strategies are available. The advent of tissue engineering may hold the key for this group of patients.

Tracheomalacia and bronchomalacia

Tracheomalacia is a condition in which there is reduced stiffness of the tracheal wall, resulting in abnormal collapse of the trachea during expiration which, if severe, can produce symptoms of airway obstruction. Bronchomalacia is the equivalent condition affecting the bronchi. There is, however, no association between tracheobronchomalacia and laryngomalacia, although because the latter is a common condition it may sometimes coexist.

Pathologically, the striking finding is an increased muscle-to-cartilage ratio seen on the transverse section of the trachea; in other words, a widening of the trachealis relative to the cartilage rings, which become C-shaped instead of horseshoe-shaped. Normally, the ratio is 1:4 or 1:5, but in tracheomalacia it may be closer to 1:2. However, in children the trachea and bronchi are more compliant than in the adult and some degree of collapse may be observed during endoscopy in normal children. This is particularly obvious if the level of general and topical anaesthesia is too light and the child tends to cough and strain in consequence, often with anterior bulging of the trachealis. To be clinically significant, more than 50% obstruction is probably required, as visualized at the end of expiration in the well-anaesthetized child.

Tracheomalacia is traditionally classified as primary (idiopathic), due to an intrinsic abnormality in the wall of the airway, or secondary, due to another associated anomaly or to external compression. The primary form is less common and tends to affect a longer segment of the airway. Secondary tracheomalacia is usually more localized and may be associated with TOF or laryngeal cleft or with extrinsic compression by an anomaly of the great vessels or a mediastinal mass. A common but special form of localized secondary tracheomalacia is the suprastomal collapse which arises above most long-standing paediatric tracheostomies, produced by pressure from the convexity of the tracheostomy tube.

The stridor of tracheomalacia becomes apparent during the first few weeks of life and consists of a very variable high-pitched expiratory noise. This may be accompanied by a harsh, barking cough, especially in the localized form of the condition. Characteristically, the stridor becomes much worse when the child is active, feeding, upset, coughing or crying, and it may be associated with cyanotic attacks which are sometimes sufficiently severe to be termed 'dying spells'. The pathophysiology of these seems to be that, with vigorous respiration, airflow through the trachea increases and in accordance with Bernoulli's principle the pressure within the airway correspondingly falls. This encourages further collapse of the malacic segment and a vicious circle is established that can result in complete collapse of the trachea with respiratory obstruction. These episodes are probably self-limiting but, faced with total obstructive apnoea and cyanosis, parents and caregivers will usually attempt resuscitation rather than wait and see.

The stridor of tracheobronchomalacia is typically episodic, thus on examination the child may seem perfectly well. There may be a prolonged expiratory phase to respiration, possibly with faint expiratory stridor. However, crying or feeding can dramatically change the picture to one of an infant who is clearly obstructed and in respiratory distress.

Plain X-rays are not usually helpful. A barium swallow may identify a TOF and can also demonstrate the airway collapse on lateral screening. Echocardiography may be useful in defining any suspected anomaly of the heart and great vessels. CT angiogram is extremely useful for identifying the cause of extrinsic compression of the trachea by normal or abnormal vessels, including vascular rings. Contrast bronchography may be the most useful radiological investigation: it is a dynamic study that not only demonstrates the areas of collapse but enables the opening pressures to be measured, which is extremely helpful in setting continuous positive airway pressure (CPAP) levels for children with very severe tracheobronchomalacia who are intubated or have undergone tracheostomy. Even if tracheobronchomalacia has been demonstrated radiologically, it is nonetheless important to undertake a full MLB to examine the collapse directly and exclude other abnormalities such as a TOF or laryngeal cleft. Typically, anterior tracheal wall collapse will be observed, with flattened tracheal rings and a wide trachealis (**Figure 30.10**). In addition, the common vascular anomalies have sufficiently characteristic features to aid diagnosis (see below).

Mild tracheobronchomalacia (less than 75% collapse) requires no intervention, and the stridor can be expected to resolve spontaneously by around the age of 2 years. However, parents will require careful explanation and reassurance, as well as being taught cardiopulmonary resuscitation if their child is prone to 'dying spells'. Severe tracheobronchomalacia (more than 75% collapse) may require treatment, especially if associated with failure to thrive. If it is secondary to a vascular anomaly, this should be corrected. The severe localized tracheomalacia often associated with a TOF usually responds well to an aortopexy, whereby the aorta is sutured to the back of the sternum. If this fails, an extended tracheostomy tube will effectively support a midtracheal malacic segment, but this is not a satisfactory solution for lower-end tracheal or for bronchial collapse. For the infant in intensive care with severe primary tracheobronchomalacia who cannot be weaned off CPAP, it may be necessary to resort to a tracheostomy in order to apply long-term CPAP. Alternative surgical solutions for this most severe end of the disease spectrum have been sought by cardiothoracic surgeons: these include internal or external stenting of the trachea, segmental resection and cartilage grafting, but all present formidable difficulties and complications with very variable outcome, and the risks may exceed those of the condition itself.

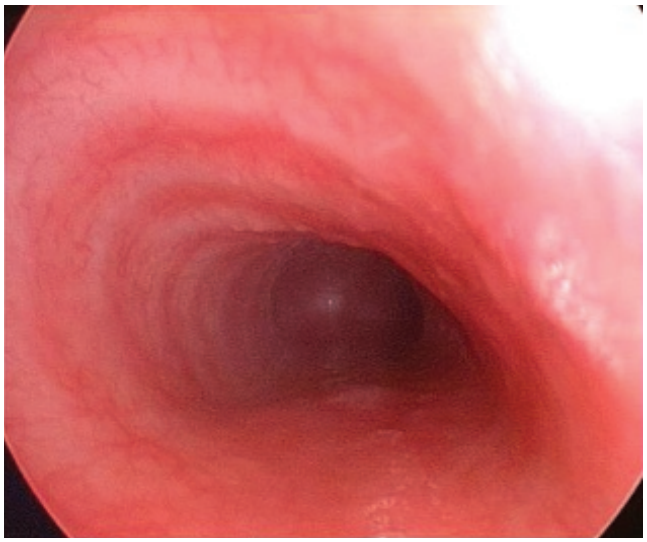

Figure 30.10 Tracheomalacia caused by external compression from an aberrant innominate artery.

Tracheo-oesophageal fistula

Tracheo-oesophageal fistula is a fairly common congenital malformation of the neonatal air and food passages, which usually occurs in association with oesophageal atresia. Eighty-seven per cent of cases have oesophageal atresia with a TOF communicating between the distal oesophagus and the mid- to lower trachea or a main bronchus. The remainder have oesophageal atresia without a TOF (6%); atresia with a proximal TOF (2%); atresia with a proximal and distal TOF (1%); or a TOF without atresia ('H-type fistula') (4%). Approximately 50% of infants with TOF have additional congenital malformations, and 10–20% have tracheomalacia (see Chapter 45, Oesophageal disorders in children).

Children who present to the paediatric otolaryngologist are invariably those with an H-type fistula. Since there is no oesophageal atresia, they are the least symptomatic of the group, with no swallowing difficulty, but small amounts of fluid pass through the fistula into the trachea and produce symptoms and signs of recurrent minor aspiration. The diagnosis is usually established by a barium

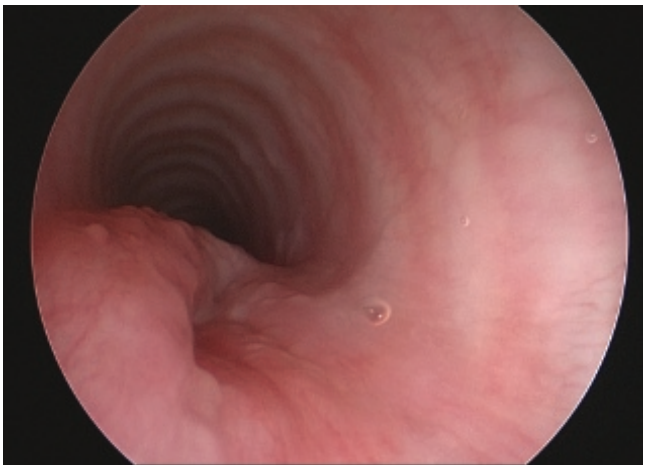

Figure 30.11 Tracheosophageal fistula seen at bronchoscopy.

swallow, but even thin contrast may not pass through a tiny fistula. In such cases MLB is required to identify the tracheal opening, which is typically characterized by a V-shaped mucosal fold around it in the posterior wall of the trachea (**Figure 30.11**). Treatment is by ligation and division of the fistula.

For further details on the management of TOF, see Chapter 101, Diseases of the oesophagus, swallowing disorders and caustic ingestion.

Vascular compression

It is estimated that 3% of the population have an anomaly of the great vessels, but only a few of these have symptomatic airway compression.[46] Such vascular anomalies are classified into vascular rings, which completely encircle the trachea and oesophagus, and vascular slings, which exert non-circumferential pressure.

VASCULAR RING

The commonest vascular ring is a double aortic arch. In this abnormality the ascending aorta divides into two arches, one of which passes to the right of the trachea and the other to the left, reuniting posterior to the oesophagus to form the descending aorta on the left. The left arch is usually smaller than the right, and the configuration of the main branches is variable, but the result is compression of both the trachea and the oesophagus, producing stridor, dyspnoea, dysphagia and a brassy cough.

A less common and less constricting ring is produced when there is a right-sided aortic arch and descending aorta associated with an aberrant left subclavian artery. In this situation the ring is completed by the ligamentum arteriosum which passes to the left of the trachea, connecting the descending aorta to the pulmonary trunk.

Patients with vascular rings tend to present earlier in life and with more severe airway symptoms than those with vascular slings. A barium swallow is diagnostic, showing a characteristic double impression upon the column of contrast, and an echocardiogram will confirm the anomaly. Surgical treatment, almost always necessary, is by dividing the lesser component of the ring, but there is invariably a localized area of tracheomalacia produced by the compression which may persist for months or even years.

VASCULAR SLING

The commonest vascular sling is an aberrant innominate artery. The artery arises further to the left and more posteriorly than usual, and crosses the anterior surface of the trachea obliquely just above the carina from the left inferiorly to the right superiorly.

Cases usually present during the first year of life with less severe airway obstruction than that caused by vascular rings. Typically, there is expiratory stridor, cough, recurrent chest infection and sometimes reflex apnoea. The bronchoscopic appearances are diagnostic, with a characteristic sloping, pulsatile compression of the trachea 1–2 cm above the carina which is most marked on its anterolateral aspect (see **Figure 30.10**). Upward pressure with the tip of the bronchoscope compresses the artery against the sternum and obliterates the right radial pulse. In severe cases, surgical relief of the obstruction is necessary: this can be achieved either by aortopexy, in which the vessel is suspended anteriorly from the sternum, or by reimplanting it further to the right on the aortic arch.

A 'pulmonary artery sling' is produced by an anomalous left pulmonary artery, which arises on the right and passes between the trachea and oesophagus, compressing both (**Figure 30.12**). This may be associated with lower-end tracheal stenosis which sometimes also involves the

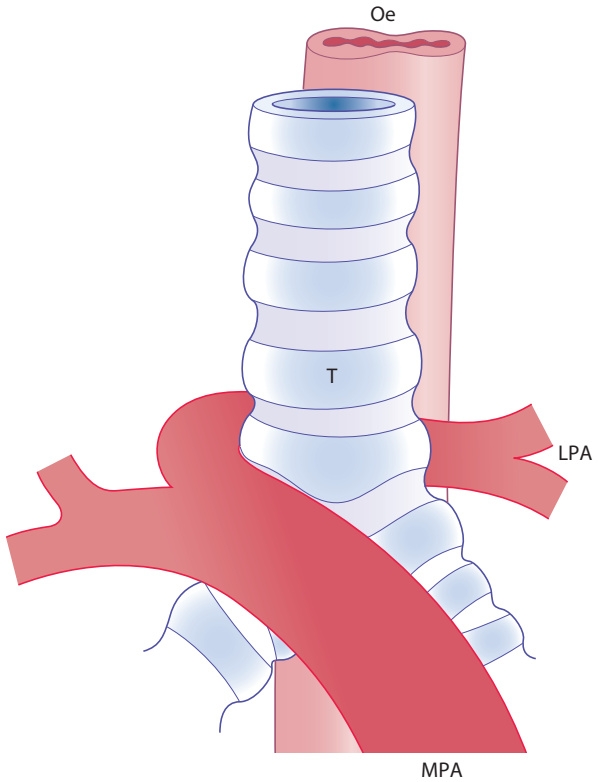

Figure 30.12 Diagram of a pulmonary artery sling. LPA, left pulmonary artery; MPA, main pulmonary artery; Oe, oesophagus; T, trachea. Redrawn with kind permission from C.M. Bailey and Springer Science and Business Media.[18]

carina and right main bronchus. Surgical reanastomosis may be needed to relieve the compression.

Enlargement of the pulmonary artery in association with a cardiac defect can also produce compression of the distal trachea and bifurcation. An aberrant right or, more rarely, left subclavian artery passing posterior to the oesophagus will compress the oesophagus alone, and so produces dysphagia but no stridor.

Anomalous bifurcations

The right upper lobe bronchus may take origin from the right lateral wall of the trachea above the carina, and is termed a tracheal bronchus or suis bronchus. This is the normal arrangement in a pig and so the anomaly in humans is often referred to as a porcine or 'pig' bronchus. It is usually an asymptomatic, incidental finding, but may sometimes be associated with tracheal stenosis. Minor alterations to the distal bronchial branching pattern are not unusual and, likewise, do not usually cause problems.

Congenital cysts and tumours

Tracheogenic and bronchogenic cysts are thought to originate from evaginations of the primitive tracheal bud and are sometimes termed reduplication anomalies. They may happen anywhere along the tracheobronchial tree: they are lined with respiratory epithelium, filled with mucus, and their walls may contain any elements of normal tracheobronchial wall. Bronchogenic cysts may communicate with the airway.

Some patients are symptom-free, but large cysts or those that become infected cause non-pulsatile compression of the airway and present with symptoms, signs and endoscopic appearances otherwise similar to those produced by vascular compression (see 'Vascular compression' above). CT or MRI will demonstrate the lesion clearly, and treatment is by thoracotomy and surgical excision.

Thymomas or teratomas may produce airway compression in the neck or mediastinum. CT or MRI is needed to define the size and situation of the mass prior to surgical excision.

BEST CLINICAL PRACTICE

- ✓ The diagnosis of mild laryngomalacia can be confirmed in the outpatient clinic by flexible fibre-optic laryngoscopy.
- ✓ Microlaryngoscopy and bronchoscopy under general anaesthesia are necessary if the stridor in laryngomalacia is severe, there is failure to thrive or any atypical features.
- ✓ Propranolol has become the first-choice treatment for subglottic haemangiomas, although surgical excision remains as a viable alternative for isolated, non-circumferential lesions.
- ✓ Slide tracheoplasty is the treatment of choice for long-segment congenital tracheal stenosis.
- ✓ Management of congenital disorders of the larynx, trachea and bronchi requires the multidisciplinary resources of a major children's centre.

FUTURE RESEARCH

- ➤ The rarity and often life-threatening nature of many congenital disorders of the larynx, trachea and bronchi means that evidence for their management tends to be confined to evidence levels 3 and 4. International collaboration between large centres is often the only way to generate sufficient patient numbers to generate evidence in this field.
- ➤ Advances in the field of airway regenerative medicine means that tissue engineering is becoming a realistic potential therapy for congenital tracheal and bronchial malformations.

KEY POINTS

- Laryngomalacia is the most common congenital disorder of the larynx, trachea and bronchi and is the most common cause of stridor, but be aware of the possibility of coexisting pathology.
- Congenital disorders of the airway may be asymptomatic but will tend to present in the first few weeks of life with stridor and/or feeding difficulties.
- Failure to thrive raises suspicion of a congenital airway disorder.
- Congenital disorders of the larynx, trachea and bronchi are often associated with underlying syndromes and other anomalies.

CHAPTER 31

ACQUIRED LARYNGOTRACHEAL STENOSIS

Michael J. Rutter, Alessandro de Alarcón and Catherine K. Hart

SEARCH STRATEGY

Data in this chapter may be updated by a Medline search using the keywords: paediatric, laryngeal, subglottic, glottic, posterior glottic, web, supraglottic, stenosis, laryngotracheoplasty, laryngotracheal reconstruction and cricotracheal resection. The focus is on evaluation, management and surgery.

INTRODUCTION

Over the past four decades, the presentation and management of paediatric laryngeal stenosis have changed significantly. Prior to 1965, this diagnosis indicated the presence of a congenital anterior glottic web or congenital subglottic stenosis (SGS). In many children, congenital SGS was expected to improve over time. Even in children requiring tracheotomy, decannulation could be achieved within a few years without requiring laryngeal reconstructive surgery. With advancements in neonatal critical care and the introduction of prolonged intubation, this clinical scenario became less common, and acquired SGS became and remains the most frequent cause of laryngeal stenosis. This condition is generally more severe than congenital SGS and typically does not improve over time. Modern paediatric laryngeal reconstruction was thus born of necessity to manage these otherwise healthy, but tracheotomy-dependent children.

Further improvements in neonatal care, particularly the use of nasopharyngeal continuous positive airway pressure (CPAP) and high-flow nasal cannulae, have led to a significant decline in the incidence of acquired SGS in children without other medical problems. These improvements have resulted in the salvage of premature and often medically fragile children whose laryngeal pathology is but one component of a myriad of health issues. The typical child who now presents with SGS is more likely to have problems associated with extreme prematurity or genetic or other birth defects. The management of these children is complex, ideally requiring an interdisciplinary team approach. In addition, their laryngeal pathology is more severe, with stenosis potentially involving not only the subglottis but also the supraglottis or glottis; while SGS is far more common, combined pathology is not uncommon.

Although the complexity and multifaceted needs of children with SGS have increased, so too have the management strategies used to treat these children. Endoscopic procedures, particularly balloon dilation, new open operative techniques (e.g. slide tracheoplasty), and new uses for medications (e.g. azithromycin and topical antibiotic and steroid combinations), have all made contributions to patient care.

Despite these advances, acquired laryngeal stenosis continues to cause significant morbidity and mortality, whether or not patients are tracheotomy-dependent. The primary aim of intervention is decannulation or preventing the need for tracheotomy. In selected patients, voice restoration or provision of a safer airway may be the primary consideration, with decannulation being a secondary goal.

Despite the large number of centres and surgeons that care for complex children with SGS, the needs of this patient population are often highly individualized. Similarly, the experience of managing surgeons and other healthcare providers may vary widely. As such, prospective randomized controlled trials of particular treatment strategies are lacking, and most recommendations are based on level 3 or 4 evidence.

PAEDIATRIC LARYNGEAL ANATOMY

Compared with the adult larynx, the infant larynx lies high in the neck, with the hyoid bone overriding its superior aspect. The narrowest point in the infant airway is the cricoid ring. Since this is the only fixed ring within the airway, it is the most vulnerable point for iatrogenic damage caused by intubation. In a term newborn, the diameter of the subglottis is between 4.5 and 5.5 mm. If the airway diameter in the term newborn is less than 4 mm, SGS is present. A useful guideline is that the outer diameter of a 3.0 mm endotracheal tube is 4.2 mm.

The superior margin of the supraglottis comprises the superior edge of the epiglottis, the aryepiglottic folds and the arytenoids, while the inferior margin is at the level of the true vocal folds. The glottis comprises the true vocal folds and the glottic chink. In the infant, the posterior 50% of the true vocal fold consists of the vocal process of the arytenoid. The subglottis lies between the undersurface of the vocal fold and the lower border of the cricoid cartilage. The subglottic mucosa is lined with respiratory epithelium. A transition to squamous epithelium occurs at the free edge of the true vocal fold.

EVALUATION

History

A child with laryngeal stenosis may present with stridor, extubation failure or tracheotomy dependency. In each of these clinical scenarios, a meticulous initial history forms the basis for further evaluation and investigation. It is important for clinicians to determine the overall health status of the child, exploring signs or symptoms and being aware of a past diagnosis of gastro-oesophageal reflux, aspiration, lung disease or cardiac disease.

In a child presenting with stridor, the duration of stridor must first be ascertained. If acute, stridor is a medical emergency. When it is more chronic, its mode of onset should be ascertained and the determination of whether it is stable or progressive should be made. In addition, the degree of compromise to the child's lifestyle should be assessed, particularly with regard to exercise intolerance and shortness of breath on exertion. Some children will also experience obstructive symptoms during sleep. These sleep problems are usually associated with supraglottic pathology although they may be indicative of a second non-laryngeal pathology such as adenotonsillar hypertrophy. The aetiology of the child's compromised airway should also be sought, in particular any prior history of intubation. If there has been such a history, relevant details such as the duration of intubation, the temporal relationship between intubation and the onset of airway symptoms, and whether an age-appropriate endotracheal tube was used should be determined.

In an intubated child, the reason for intubation should be assessed, as should any medical problems that could contribute to extubation failure. The relevant history should include the length of time the child was intubated, the size of the endotracheal tube, the number of attempts at extubation and whether extubation failure abruptly occurred following endotracheal tube removal or was due to gradual and progressive respiratory compromise necessitating reintubation.

In a child with tracheotomy dependency, the aetiology requiring initial placement of a tracheotomy should be ascertained and the duration of cannulation and size of the tracheotomy tube should be determined. Any history of airway reconstructive surgery is also extremely important. Another significant aspect of a thorough assessment is an evaluation of voice quality and the ability to tolerate a speaking valve.

Physical examination

Once a case history has been taken, the presence of stridor and retractions at rest should be assessed. The nature of the stridor — in particular whether it is purely inspiratory, expiratory or biphasic — should be noted. Nonetheless, retractions provide a better barometer of obstruction than stridor. Assessment of voice quality is particularly important in that it may provide an indication of the anatomic region of the pathology. Children with supraglottic stenosis usually present with a characteristic muffled or 'throaty' voice, while those with anterior glottic webbing tend to have a very hoarse voice. Those with posterior glottic stenosis and SGS usually have normal voice quality. In a child presenting with extubation failure, non-laryngeal causes such as nasal obstruction and glossoptosis are explored. In cases of tracheotomy dependency, the size of the tracheotomy tube, the child's ability to tolerate a speech valve and the possibility of tracheotomy tube plugging are pursued.

Imaging studies

Radiologic evaluation of the paediatric airway is most helpful in patients who are neither intubated nor tracheotomy-dependent. Imaging studies fall into two time-related categories: those that are performed prior to endoscopic evaluation and those that are best after endoscopic evaluation. Prior to endoscopy, soft-tissue airway films of the neck and chest should be performed in both lateral and anterior/posterior projections. These are useful in evaluating laryngeal stenosis and may also give timely warning of a possible tracheal stenosis. Anterior/posterior and lateral chest films indicate possible underlying lung pathology. A barium swallow study may not only provide information on the ability to swallow and the relative risk of aspiration but may also indicate the need to evaluate the airway for a posterior laryngeal cleft or a tracheo-oesophageal fistula. In addition, it may provide information on a child's propensity to gastro-oesophageal reflux, vascular compression of the airway and the presence of an oesophageal foreign body.

After endoscopic airway evaluation, more directed imaging studies are valuable. Spiral computed tomography (CT) scanning of the airway with contrast enhancement

provides a useful view of intrathoracic vasculature. If relevant, 3D reconstruction of CT axial images may be valuable in evaluating the intrathoracic airway. Although both magnetic resonance imaging (MRI) and magnetic resonance angiography (MRA) also provide excellent views of intrathoracic vascular anatomy, they require more time to perform and are more likely to require sedation or anaesthesia. In younger children, CT and MRI airway evaluation may complement endoscopic evaluation; however, they are not a substitute for it.

In children with upper airway compromise, sleep fluoroscopy or cine MRI may provide a valuable dynamic airway assessment.

Endoscopic airway evaluation

FLEXIBLE NASOPHARYNGOSCOPY

In a child who has not been evaluated previously, flexible nasopharyngoscopy with the child awake should be performed prior to rigid endoscopy. Although the nasal passages, nasopharynx, oropharynx, supraglottic and glottic airway should be assessed, and pathology such as choanal atresia, adenoid hypertrophy, tonsillar hypertrophy and laryngomalacia should be evaluated, the most important information to be sought relates to vocal cord movement. The ability of the vocal cords to normally abduct is critical information prior to any consideration of laryngeal reconstructive surgery, whether movement is compromised by unilateral or bilateral vocal cord paralysis, posterior glottis stenosis, or cricoarytenoid joint fixation. Although the risk of inducing laryngospasm is low, it is recommended that the nasopharyngoscope should not be advanced below the level of the glottis. Although the precise mechanism is unclear, even children with bilateral true vocal fold paralysis may have laryngospasm.

RIGID ENDOSCOPY

It must be emphasized that evaluation of the paediatric airway should not be considered a minor procedure, particularly when performed in a child with an unstable airway (see Chapter 28, Stridor). Extreme care must be taken not to exacerbate the child's condition. The surgical and anaesthetic team must work together closely and must have specific knowledge of the paediatric airway and of appropriate instrumentation. In a child with a compromised airway who does not have a tracheotomy tube, preoperative administration of dexamethasone, 0.5 mg/kg up to a maximum of 20 mg, is a prudent precaution.

Rigid endoscopy remains the 'gold standard' for paediatric airway evaluation, and this evaluation should begin with an assessment of the supralaryngeal airway. The possible presence of retrognathia and any associated glossoptosis or difficulty of laryngeal exposure should be initially assessed, as should tonsillar hypertrophy or evidence of pharyngeal scarring. The supraglottic larynx should be carefully assessed for scarring, laryngomalacia, short aryepiglottic folds and arytenoid prolapse. The glottis should be evaluated for scarring, anterior glottic webbing and posterior glottic stenosis, and care should be taken to exclude the presence of a posterior laryngeal cleft. If vocal motion is clearly seen, it can be assumed that neither true vocal cord is paralyzed. If, however, movement is not observed, nasopharyngoscopy with the patient awake should be performed. The subglottis should be evaluated, and any stenosis or scarring noted. If stenosis is present, its severity, length, position and physical characteristics should be noted. It may be characterized as soft or firm, as concentric or with lateral shelving, and with mucosa appearing either quiescent or actively inflamed.

If there is a sufficient lumen to allow passage of the endoscope, the trachea is next assessed. Hopkins rod endoscopes with an outer diameter as small as 1.9 mm are available, and can negotiate most grade III SGS. An assessment is made of the upper trachea, including the tracheotomy stoma site, looking for suprastomal collapse or the presence of a suprastomal granuloma. Assessment is also made of possible tracheomalacia and vascular compression of the airway. Although complete tracheal rings are rare, their possible presence should be evaluated cautiously, so as not to induce oedema within an already compromised segment of airway. The carina and mainstem bronchi are also evaluated.

If SGS has been identified, the area of stenosis should be graded according to the Myer–Cotton classification[1] (see **Table 31.1**). This is best carried out utilizing endotracheal tubes, with a small tube being placed initially. If this tube leaks at less than 20 cm of water pressure through the subglottis, the next larger size is placed. It should be noted that the Myer–Cotton grading system is not designed to address supraglottic, glottic or tracheal stenosis (**Figure 31.1**).

ANAESTHETIC TECHNIQUE DURING BRONCHOSCOPY

A collaborative relationship with the anaesthetist is essential in deciding upon the specific anaesthetic technique to be used when performing rigid endoscopy. Possible options include spontaneous ventilation, assisted ventilation, jet ventilation, total intravenous anaesthesia (TIVA) and apnoea with intermittent bag and mask ventilation. Spontaneous ventilation offers the best dynamic assessment of the airway and is thus recommended. Endoscopy may be performed with the laryngoscope introduced into the airway and suspended in position. This frees both the surgeon's hands for introduction of a telescope and instruments as required. Some surgeons prefer to expose the larynx with an anaesthetic laryngoscope blade held in one hand and use the other hand to introduce a telescope. Endoscopy may also be performed with a ventilating bronchoscope or a Hopkins rod telescope, keeping in mind that the technique itself is not as important as the information gained. We prefer to use the Hopkins rod telescope, exposing the larynx with a straight anaesthetic laryngoscope blade. The child spontaneously ventilates a mixture of sevoflurane and oxygen through an endotracheal tube placed in the oropharynx, and with additional intravenous anaesthesia provided by propofol bolus.

TABLE 31.1 The Myer–Cotton classification (redrawn from Myer et al.,[1] with permission)

Grade	From	To	Examples
I	 No obstruction	 50% obstruction	
II	 51% obstruction	 70% obstruction	
III	 71% obstruction	 99% obstruction	
IV	No detectable lumen		

FLEXIBLE BRONCHOSCOPY

In selected children, flexible bronchoscopy may complement rigid bronchoscopy and both may occasionally be required to evaluate a child's airway adequately. Also, in many instances, these techniques can be used interchangeably. In some cases, however, each technique offers clear advantages. Rigid bronchoscopy provides a superior assessment of the larynx, especially the posterior glottic area. Flexible bronchoscopy is often extremely valuable in assessing a larynx that is difficult to access with rigid instrumentation and may provide valuable information about airway dynamics, such as the degree of pharyngeal collapse, glossoptosis and the presence of laryngomalacia, tracheomalacia or bronchomalacia. Flexible bronchoscopy also permits evaluation beyond the eighth generation of bronchi in older children and allows specific lavage of bronchial subsegments, which may provide information about silent aspiration if lipid-laden macrophages are found.

Gastrointestinal evaluation

OESOPHAGOGASTRODUODENOSCOPY, OESOPHAGEAL BIOPSY AND PH PROBE

In selected cases, particularly in patients with complex underlying medical conditions or in those who have failed previous airway reconstruction, oesophagogastroduodenoscopy may be beneficial in the assessment of a child prior to airway reconstruction. It can provide information about oesophagitis, gastritis, and the status of the lower oesophageal sphincter, especially in regard to whether a previous fundoplication is still functional.

Pre-operative evaluation of gastro-oesophageal reflux with dual probe pH or impedance monitoring and/or oesophageal biopsy is advisable and should be mandatory in a child with an active larynx or recalcitrant airway stenosis following previous reconstruction.[2] Oesophageal biopsy will also provide information about oesophagitis,

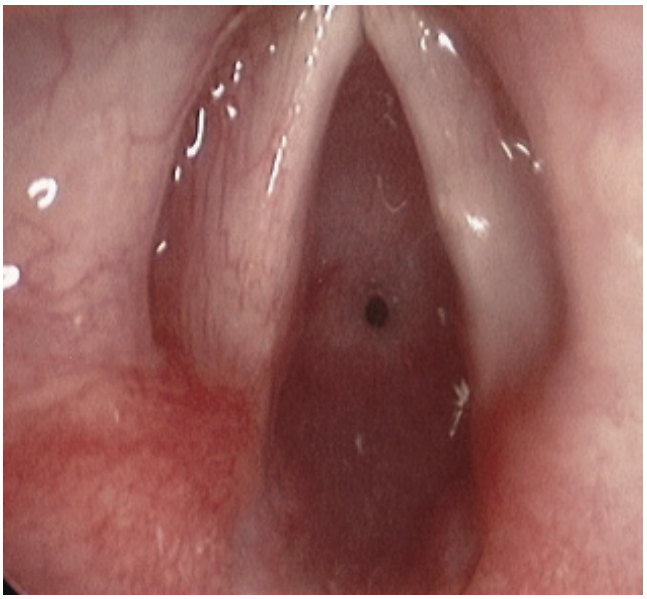

Figure 31.1 Grade III acquired subglottic stenosis.

including the possibility of eosinophilic oesophagitis, and is currently the best method of diagnosing and monitoring this condition.

Placement of a pH or impedance probe may be done at the time of oesophagogastroduodenoscopy, at the time of bronchoscopic evaluation, or may be performed as an elective procedure unrelated to endoscopic evaluation. Patients should be off antireflux medication for at least 1 week prior to pH probe placement. A dual pH probe with the upper port lying in the postcricoid region is desirable. While normal paediatric values for the upper port do not exist, positive readings should be viewed with suspicion. The impedance probe not only measures acid but can also provide an indication of the volume of a reflux bolus and the height in the oesophagus to which it progresses. Impedance technology also allows evaluation of non-acid reflux. This enables a child to remain on antireflux medication prior to evaluation.[3]

Evaluation of aspiration

Paediatric airway reconstruction runs the inherent risk of turning a child with laryngeal stenosis into a chronic aspirator. Although this risk cannot always be accurately evaluated pre-operatively, in most cases a thorough evaluation provides ample warning signs. Recurrent pneumonia and an insidious drop in a child's baseline oxygen saturation are highly suggestive of chronic aspiration. A history of previous aspiration or current aspiration is extremely important. In a child who is tracheotomy-dependent, copious tracheotomy secretions or secretions stained by food material indicate chronic aspiration. This is more difficult to evaluate in a child who is entirely gastrostomy (G-tube) fed. A simple solution is to intermittently place a drop of green food dye on the child's tongue and evaluate whether green-stained secretions are subsequently suctioned from the tracheotomy tube. Alternatively, a radionucleotide spit study may be performed: a drop of radioactive material is placed on the tongue and its passage is monitored to either the stomach or lung fields. In a child suspected of aspirating, a bronchoalveolar lavage, which can identify lipid-laden macrophages, may be useful. This does not, however, provide useful information in a child who is wholly G-tube fed. Children with grade IV SGS, in whom aspiration is not possible prior to laryngotracheal reconstruction, present a particular challenge. In these children, pre-operative evaluation to assess the relative risk of aspiration is strongly advocated.

A barium swallow or video swallow study may provide information not only on the presence of aspiration, but also on what substances are most likely to be aspirated. Thin fluids are more likely to be aspirated than purees or solids.

A functional endoscopic evaluation of swallowing, whereby the larynx is visualized with a nasopharyngoscope while a child swallows food or drink, can provide valuable information about the relevant risk of aspiration and the mechanism of aspiration as well as the presence or absence of normal laryngeal sensation.

Having knowledge of the possibility of post-operative aspiration allows for appropriate pre-operative counselling and management to minimize this risk. Innately, there are three things that may be aspirated, namely food and drink presented by mouth, saliva and gastric reflux. The respective risk of each can be minimized by conversion to G-tube feeding, reducing saliva production through a 'drool' procedure, and performing a fundoplication. Most children and families presented with the choice of a gastrostomy tube or a tracheotomy tube will choose the former.

Sleep evaluation

A formal sleep evaluation may be a useful method to evaluate a child's respiratory efforts and oxygen needs, whether or not a tracheotomy is in place. The primary aim of laryngotracheal reconstruction is decannulation, and this operative procedure is rarely warranted if decannulation cannot be achieved. In children with tracheotomy dependency, it is important to evaluate whether surgical correction of laryngeal stenosis will permit decannulation. In children with significant lung disease, particularly bronchopulmonary dysplasia or in those who are dependent on a ventilator or CPAP, decannulation may be imprudent. Similarly, children with progressive neuromuscular disorders, diaphragmatic weakness or central hypoventilation syndrome may not be candidates for decannulation. If results of a sleep evaluation indicate pulmonary compromise that precludes decannulation, laryngeal reconstruction may be futile.

Voice evaluation

Voice evaluation in children with laryngeal stenosis, tracheotomy dependency or following laryngotracheal reconstruction is in its infancy and is poorly understood. It is clear, however, that laryngeal reconstruction frequently has a negative impact on the voice, particularly

in children requiring supraglottic or glottic surgery and in those in whom a laryngofissure is required to reconstruct the airway. What is unclear is which underlying pathologies and reconstructive procedures place the voice at greatest risk, and also the extent to which a voice disorder relates to the initial aetiology of the laryngotracheal stenosis.

Children have a tremendous drive to communicate, which often compensates for severe anatomic dysfunction. Some children will retain a surprisingly good-quality voice, even with a grade III SGS. However, children with a grade IV SGS are aphonic unless they have learned oesophageal speech techniques. In these children, laryngotracheal reconstruction may be extremely beneficial in terms of regaining voice, even if decannulation is not achieved.

CONSIDERATIONS PRIOR TO LARYNGEAL RECONSTRUCTION

Surgical intervention for laryngeal stenosis is not always warranted, and the decision as to whether or not to perform such surgery is generally predicated by the overall health status of the child rather than by the stenosis itself. In a child with a high risk for aspiration or with certain craniofacial anomalies, surgical reconstruction may be inappropriate in that the laryngeal stenosis may actually protect the lungs from aspiration. In some children, ongoing aspiration may lead to a consideration of laryngotracheal separation rather than laryngeal reconstruction. Similarly, in children with other significant medical conditions, such as those requiring CPAP, bilevel positive airway pressure (BiPAP) or ventilator support, reconstruction is unwise. While not universally accepted or rigorously proven, most experts in paediatric laryngotracheal reconstruction believe that gastro-oesophageal reflux disease is both a cofactor for the development of SGS and a negative influence on the outcome of operative reconstruction. Oxacillin or methicillin-resistant *Staphlococcus aureus* (MRSA) screening prior to open airway surgery is also recommended, as post-operative infection may greatly compromise the surgical repair. Although a child with a progressive neuromuscular disorder may be considered for laryngotracheal reconstruction to improve vocal function, this seldom enables long-term decannulation.

In some children, a period of observation prior to considering surgical intervention is the best course of action. This strategy is most appropriate in a child with an active or inflamed larynx that is not amenable to medical intervention. An active larynx is generally related to gastro-oesophageal reflux disease or eosinophilic oesophagitis and is, therefore, potentially amenable to such intervention. In children in whom the aetiology of an active larynx is unknown, laryngeal reconstruction is unwise until the laryngeal inflammation has improved. In some of these children, azithromycin given as an anti-inflammatory drug on a Monday, Wednesday, Friday dosing regimen may be effective in reducing inflammation in up to 50% of children with an idiopathic active larynx. In children who do not respond to azithromycin, spontaneous resolution often occurs within a 1- to 2-year period. A waiting period is also advisable in a child who has recalcitrant stenosis after a recent airway reconstruction, or in a child whose larynx is healing from laryngeal trauma. While only a guideline, a 6-month 'cooling off' period is often advisable in such children.

Although weight is a less important factor than the overall health status of a child and the child"s laryngeal disease, it is a frequently used criterion for postponement of airway reconstruction. While laryngotracheal reconstruction can be effectively performed in children less than 3 kg if other criteria permit, a 10 kg guideline is often used. Nevertheless, airway reconstruction in a larger child is technically much easier to perform.

The child with complex medical problems

Historically, children presenting for airway reconstruction were otherwise healthy children with a stenosed larynx. Increasingly, however, children presenting for airway reconstruction have multifaceted complex medical problems, most commonly related to either extreme prematurity or syndromic conditions (see Chapter 5, The child with special needs). In such children, an interdisciplinary team approach is advisable for adequate assessment both before and after planned reconstruction. The most important decision to be made is whether it is advisable to even attempt reconstruction. If so, consideration must be given to other interventions indicated prior to proceeding with laryngeal reconstruction. In a child with reflux disease, a fundoplication may be required. In a child with aspiration, a 'drool' procedure may be required. It is prudent to have most of these children undergo additional evaluation by paediatric subspecialists in pulmonology, gastroenterology, medical genetics and neurology. Pre-operative evaluation and optimization improve outcomes.

THERAPY

Medical therapy

When the larynx is stable and quiescent, there is no role for medical therapy. In the inflamed or active larynx, however, medical therapy plays an important role in alleviating laryngeal inflammation; in turn, this enhances the potential for a successful operative outcome. In children with SGS, medical therapy alone occasionally obviates the need for laryngeal reconstruction by providing sufficient improvement to permit decannulation.

Medical therapy for an inflamed larynx revolves around treatment of gastro-oesophageal reflux disease or eosinophilic oesophagitis. If reflux is diagnosed or even suspected, then a low threshold for treatment with H_2 antagonists or proton pump inhibitors is recommended. In children with recalcitrant acidic reflux or significant non-acid reflux, consideration should be given to performing fundoplication.

A recent observation has been the correlation between eosinophilic oesophagitis, laryngeal inflammation and a poor outcome following laryngotracheal reconstruction.[4] Eosinophilic oesophagitis has a characteristic appearance on oesophagogastroduodenoscopy, with oesophageal furrows often having microscopic white plaques noted. However, the definitive diagnosis is made on biopsy, with greater than 20 eosinophils per high-power field being noted. In children with eosinophilic oesophagitis, evaluation for underlying food allergies is indicated. In children in whom a food allergy is not proven, treatment with oral fluticasone is suggested. An initial dosing regimen of 440 µg, sprayed on the tongue twice a day and swallowed, is usually efficacious. Follow-up oesophagoscopy with further biopsies to confirm resolution of disease is suggested prior to undertaking laryngeal reconstruction, which is usually delayed for 6 months.

Tracheotomy

In a child with an unsafe or unstable airway in whom laryngotracheal reconstruction is not immediately advisable, temporary placement of a tracheotomy tube is advisable to secure an adequate airway until laryngeal reconstruction can be performed. Placement of a tracheotomy should be performed with a view to the subsequent laryngeal reconstruction that may be required. A high tracheotomy close to the cricoid increases the risk of exacerbation of stenosis, but it may make subsequent cricotracheal resection (CTR) simpler, as a shorter segment of airway can then be resected. Tracheotomy through the second to fourth tracheal rings is still recommended.

Although a tracheotomy provides a safer airway in a child with laryngotracheal stenosis, the airway is by no means completely safe. Tracheotomy-related deaths continue to occur in children who could otherwise anticipate good long-term quality of life, and the greater the degree of obstruction, the greater the risk. A tracheotomy is a marked compromise on both a child's and a family's quality of life and emotional health.

Endoscopic management of subglottic stenosis

A range of endoscopic and open procedures are currently used for the management of SGS, and these approaches are not always mutually exclusive. Endoscopic approaches are used both as the primary treatment modality and as an adjuvant treatment before or after open airway reconstruction. Children with grade I or II stenosis and no history of endoscopic failure have a higher likelihood of successful endoscopic management, whereas those with more severe SGS or multilevel stenoses are more likely to require open reconstruction.[5, 6]

Although dilation has a considerable history, balloon dilation has been widely adopted only over the last decade, and bougienage dilation, with associated mucosal trauma caused by the shear forces inevitable with this technique, has fallen from favour.

Balloon dilation of the airway using high-pressure non-compliant balloons has evolved considerably in recent years and is now considered an invaluable addition to the tools used to manage SGS,[7–11] reportedly reducing the need for open airway surgery by as much as 80%.[10] Balloons offer a number of advantages, as they exert a purely radial force over the circumference of the stenosis, thus minimizing the risk of airway rupture or mucosal trauma. Pressures of over 20 atmospheres may be applied by some balloons. By using a device that incorporates a pressure gauge, they also allow the surgeon to fine-tune the force applied to the stenosis. A third advantage is that balloon dilation catheters are long, narrow and flexible — all of which allow the surgeon to steer through a severe stenosis. Selection of balloon size is based on the expected size of the normal airway. For example, a 4 year-old should be intubated with a 5.0 mm endotracheal tube with an outer diameter of nearly 7 mm. The balloon size selected would be 7–8 mm for the larynx. For tracheal lesions, balloon selection is typically 1 mm greater than the size predicted for the larynx. Repeated dilation at 1- to 3-week intervals on up to four occasions is recommended. Adjunctive interventions such as steroid injection and scar division may provide additional benefit, especially in patients with established thicker stenosis. Scar division may be performed utilizing a sickle knife, microlaryngeal scissors or a laser. In selected patients, subglottic or tracheal scarring may be divided prior to balloon dilatation (**Figure 31.2**).

Appropriate patient selection for balloon dilatation is critical to a successful outcome. Children who are likely to respond well to this technique are those with thin or web-like and soft stenoses consisting of immature scar tissue. In contrast, patients with firm or mature scar tissue, cartilaginous airway narrowing, and structural problems of the airway exoskeleton (e.g. subglottic lateral shelves, missing cartilage) are less likely to respond.[11] Dilation is also less likely to yield positive outcomes in longer stenoses and in patients with additional airway lesions.[11]

The recommended technique for balloon dilation is having the patient not be forcefully breathing during the procedure; therefore, after an initial evaluation of the airway, the patient is pre-oxygenated and then either briefly paralyzed or given a bolus of propofol to minimize spontaneous respiration. The balloon is introduced with direct visualization with a Hopkins rod endoscope, and then inflated to the rated burst pressure. Care should be taken that the balloon does not displace (watermelon seeding). The balloon is kept inflated for 2 minutes or until the patient desaturates to 90%, and it is then deflated and removed.

The potential complications of balloon dilation are rare. Negative pressure pulmonary oedema may occur with forced respiratory attempts against a closed glottis. Airway rupture may occur if an over-large balloon is selected. Distal displacement of the balloon due to watermelon seeding may occur and, if the balloon catheter is pulled and stretched trying to prevent displacement, the balloon may not be able to be deflated and may need to be ruptured with a needle or knife to remove it from the airway. Although newer balloon designs are less prone to

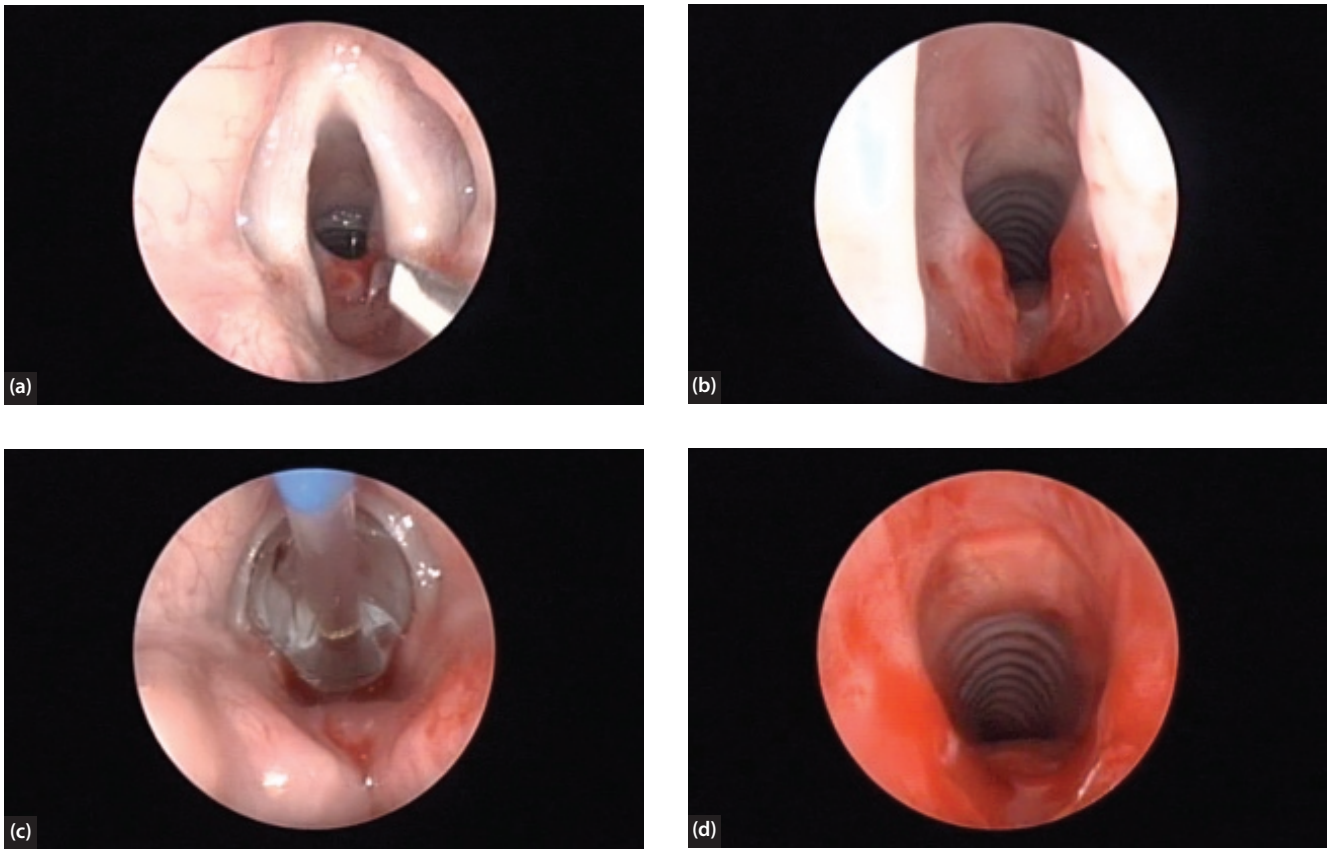

Figure 31.2 **(a)** Grade III acquired SGS immediately prior to endoscopic division with a sickle knife; **(b)** same stenosis after division in the midline posteriorly; **(c)** balloon dilatation in progress; **(d)** same child, immediately after balloon dilatation.

watermelon seeding, the main limitation of balloon dilation is that its success rate is lower than that seen with open airway reconstruction. If after four or five dilations the airway diameter has not significantly improved, then open surgery should be considered. Given that balloon dilation is relatively simple, fast and low-risk in children with mild to moderate degrees of SGS, it should be seriously considered prior to open airway reconstruction.

Laryngeal reconstruction

Laryngeal and upper tracheal reconstruction may be challenging and no single operation can adequately address all types of laryngeal stenosis. It is thus prudent to evaluate each child on an individual basis. In some patients, the most appropriate reconstruction technique may not become fully clear until the airway has been opened and the pathology directly inspected. The mainstay of laryngotracheal reconstruction is expansion cartilage grafting (**Figure 31.3**). In the subglottis, an alternative to this approach is resection and reanastomosis. Stenosis involving the supraglottis and anterior glottis is amenable to laryngoplasty without cartilage grafting. Whether congenital or acquired, tracheal stenosis may be best managed by a slide tracheoplasty (described later in this chapter).

In concept, laryngotracheal reconstruction may be managed either endoscopically or by expansion grafting, resection (tracheal or cricotracheal), or the slide tracheoplasty. Although the latter operation was conceived for the management of tracheal stenosis, it may extend into the larynx if appropriate.

GRAFTING MATERIALS

Costal cartilage is the most widely used grafting material, with excellent results noted on prolonged followup.[12, 13] It is readily available, robust, and easily shaped and carved. Moreover, it is possible to harvest more than one graft through the same incision. The usual donor site is the right fifth or sixth rib, with the incision being placed in the anticipated breast crease in girls for cosmetic reasons. The harvested graft should include the perichondrium on the lateral aspect of the graft, while leaving the inner perichondrial layer intact at the donor site to allow the potential for some cartilage regeneration. Once the graft is harvested, filling the wound with saline and performing a Valsalva manoeuvre will ensure that a breach of the pleura has not occurred. When the graft is carved to the desired shape, the perichondrium should face the lumen of the airway; lateral flanges will prevent prolapse of the graft into the airway.

When only a small graft is required, thyroid ala is a useful material. This is usually taken from the upper aspect of the thyroid cartilage on one side, at least 1 mm above the

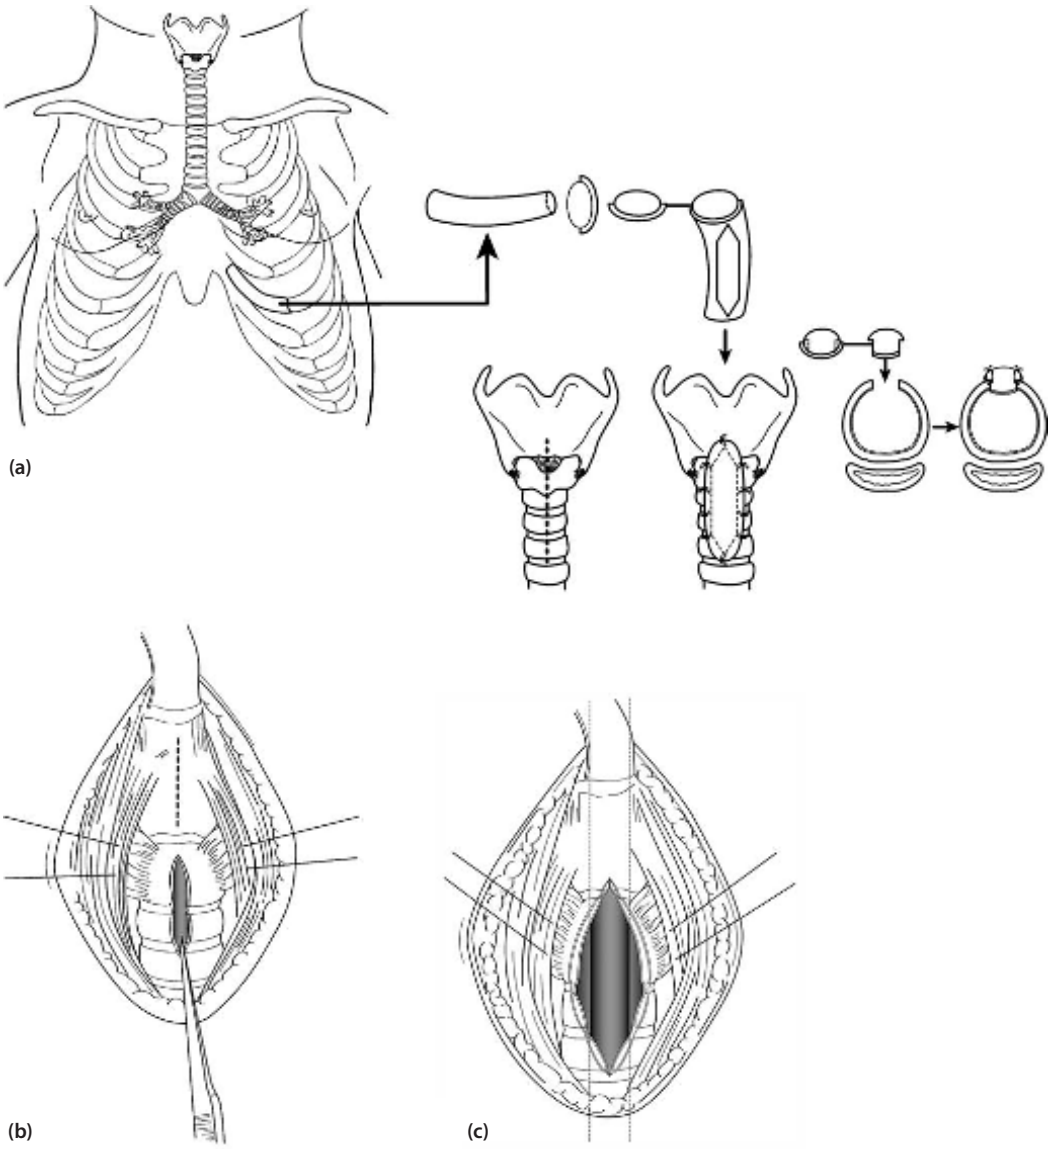

Figure 31.3 Expansion cartilage grafting.

level of the true vocal cord. Thyroid ala has the advantage of being quickly and easily harvested from within the surgical field. However, only a limited amount of grafting material is available and it is not amenable to being carved with flanges.

Auricular cartilage is also useful, in particular for the management of suprastomal collapse as part of a single-stage procedure. It is easily harvested and reasonably abundant. It makes an ideal cap or overlay graft, particularly over a stoma site, but it is comparatively weak and not appropriate for insertion between the cut edges of the cricoid. In both adults and older children, there is no cosmetic donor site deformity; however, in children younger than 1 year of age it is common to have some residual asymmetry of the ears.

Other grafting materials include buccal mucosa, septal cartilage, and a pedicled hyoid bone interposition graft. The results utilizing these grafting materials in children have been disappointing. Another described technique is the use of a clavicular periosteal graft, with its vascularity maintained by swinging the graft up on a pedicle of sternocleidomastoid muscle. This is a useful graft for older children in whom there is a significant deficit of tracheal cartilage, as after several months the graft will start to ossify, thereby providing support to the airway. In prepubescent children, the graft unfortunately seems less amenable to ossification, leaving the airway malacic.

STENTS

Not all laryngotracheal reconstruction techniques require stent placement. It may not be required in an anterior flanged graft for moderate SGS; however, it is advisable in virtually all other circumstances. Stenting maintains a lumen and prevents graft prolapse during post-operative healing, and it may remain in place for days to months. Longer-term stents are advisable when the laryngeal repair is unstable (e.g. when a posterior cricoid split has been performed in an older child without placement of a

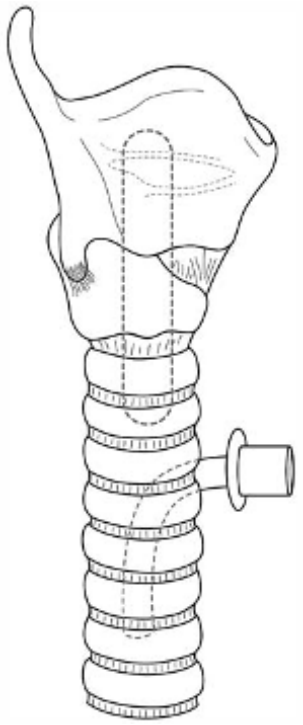

Figure 31.4 Rutter suprastomal stent.

cartilage graft) or in a recalcitrant larynx that has failed previous reconstruction. In patients in whom graft survival is threatened, such as diabetic patients and patients on continuous steroids, long-term stenting without cartilage grafts is advisable. The most commonly used stent is the silicone Rutter suprastomal stent (**Figure 31.4**), although Abouker, Monnier and Mehta stents are also available.

The Rutter stents are soft and deformable and do not interfere with placement of the tracheotomy tube. They tend to incite less granulation tissue at the distal end of the stent, and there is less dead space between the distal end of the stent and the tracheotomy tube in which scarring can occur. The proximal end of the stent is trimmed to the level of the false vocal cord and then plugged with a rounded cap that is less likely to induce epiglottic granulation tissue. Unlike the rigid Abouker Teflon stents, these soft silastic suprastomal stents may remain in place for longer than 6 weeks. There is a corresponding restriction of speech, as they permit only very limited air passage.

For longer-term stenting, tracheal T-tubes are recommended. Although T-tubes with an outer diameter of 5 mm are commercially available, because of the risk of crusting and obstruction, we do not routinely place T-tubes with an outer diameter of less than 8 mm. An 8 mm tube may be placed in a child as young as 4 years of age. Following laryngeal reconstruction, the upper end of a T-tube is generally passed through the vocal cords. Aspiration is therefore a significant risk and is expected for 2 weeks following stent placement. A supraglottic swallow technique is readily achieved by most children, minimizing the risk of aspiration. Unlike tracheotomy tubes, T-tubes cannot be easily changed. Meticulous T-tube care is thus essential.

SINGLE-STAGE RECONSTRUCTION

In children in whom a stenting period of less than 2 weeks is anticipated, an option to be considered is intubation, with the endotracheal tube acting as the stent.[14] Intubation for longer than 2 weeks, however, risks redevelopment of posterior glottic stenosis or SGS. For straightforward airway reconstruction, extubation may occur within a few days of the operation or, occasionally, even at the end of the reconstructive procedure. Although the optimal duration of intubation is not clearly defined, there has been a trend towards briefer periods of intubation following laryngotracheal reconstruction. Most children can be extubated within 2–7 days of a CTR or an anterior costal cartilage graft. Those with anterior/posterior cartilage grafts are usually intubated for 7–14 days. The older the child, the more forgiving the airway and the briefer the period of intubation required. For more complex airway surgery, a prolonged period of intubation is required.

A prerequisite for single-stage laryngotracheal reconstruction is an excellent intensive care unit (ICU) in which staff are familiar with the management of airway patients. It is undesirable for a child to have an unplanned self-extubation, and security of the nasotracheal tube is paramount. Therefore, in younger children, the use of arm restraints and sedation is usually required. Most children younger than age 3 require sedation, and children who have been previously intubated for long periods may require heavy sedation. Paralysis is undesirable, as in the event of accidental decannulation, the child is unable to maintain an airway and reintubation must be emergent. Since any child undergoing a single-stage procedure risks the need for reintubation, single-stage procedures should not be performed on children who are difficult to intubate. In the sedated child, commonly encountered problems include lung atelectasis, fluid overload from heavy sedation, pneumonia and narcotic withdrawal following extubation.

In children older than age 3 years with no major cognitive problems, sedation may not be required. Some of these intubated children may be able to ambulate, eat and visit the playroom. A fully awake child does not require ventilatory support and is less likely to have pulmonary complications from the intubation (**Figure 31.5**). The day prior to extubation, returning to the theatre to inspect the airway and downsize the tracheotomy tube is advisable (**Figure 31.6**). If the airway appears adequate to support extubation, a dose of dexamethasone, 0.5 mg/kg, is administered the night before extubation, and the patient is extubated while fully awake. Owing to the risk of laryngeal oedema, the patient should be closely observed on the ICU for the next 24 hours; oedema generally resolves within this period of time. In the event of airway distress following extubation, management options include the administration of racemic adrenaline, further steroids, helium/oxygen administration or even the use of CPAP or BiPAP. If the airway is still not adequate, the child may need to be reintubated. If so, a further trial of extubation should be performed a few days later. If this is again unsuccessful, a decision is

Figure 31.5 Single-stage laryngotracheal reconstruction. The child is intubated but awake in the intensive care unit.

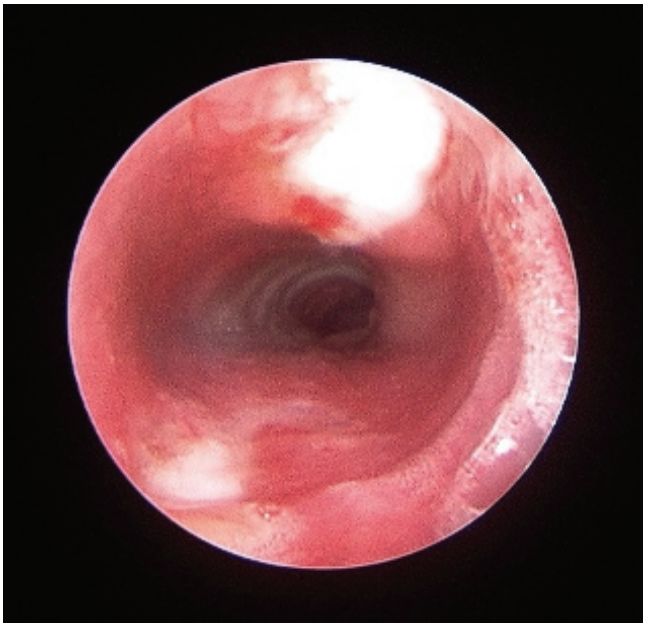

Figure 31.6 One week after single-stage laryngotracheal reconstruction the anterior and posterior costal cartilage grafts are visible but already partly covered in mucosa.

required as to whether to proceed to a third trial of extubation or to proceed with tracheotomy. If a tracheotomy is required, the stoma should ideally be placed low in the neck, below the graft site. Glottic oedema and granulation from endotracheal tube irritation are often the cause of failure during a single-stage procedure, rather than the reconstructed site itself. In such cases, the tracheotomy tube may be removed once the oedema has settled, usually within a few weeks.

The ideal patient for consideration of a single-stage procedure is one in whom a reasonably simple procedure with a stable larynx is anticipated. This single-stage approach is preferable in children in whom a tracheotomy tube has induced suprastomal collapse. Poor candidates for single-stage reconstruction include children with poor pulmonary function, those who are difficult to intubate, those with recalcitrant airway disease who have failed previous reconstruction, and those with complex disease involving multiple levels of obstruction.

Supraglottic stenosis

Supraglottic stenosis is rare, difficult to treat, and is frequently associated with supraglottic collapse. While severe supraglottic stenosis may present with stridor, the primary complaint is more commonly obstructed breathing during sleep. Therefore, a sleep study may be extremely useful in the non-tracheotomized patient or in the patient in whom the tracheotomy can be capped, even if for a brief period. The underlying aetiology is often traumatic, due to severe direct airway trauma or airway burns, or is of iatrogenic origin. Supraglottic stenosis with associated collapse is a feature of the airway that has undergone numerous laryngeal reconstructions. Visualization of the supraglottic larynx in cases of supraglottic stenosis and collapse may be misleading. Rigid endoscopic evaluation with the larynx suspended by a laryngoscope may distort the appearance of the larynx, providing false reassurance about the supraglottic airway. Flexible endoscopic evaluation with the patient spontaneously ventilating allows for superior evaluation of the airway dynamics. Nevertheless, what is observed may be deceiving. A larynx that looks extremely compromised in an anaesthetized patient may function quite adequately in the unanaesthetized state.

In children with mild to moderate supraglottic stenosis and collapse, nocturnal CPAP may be very beneficial. The most common patterns of supraglottic compromise are arytenoid prolapse and epiglottic petiole prolapse. Arytenoid prolapse is a dynamic instability of the arytenoid, either unilateral or bilateral. It is characterized by its anterior displacement during inspiration, which may cause significant airway obstruction. This problem most commonly follows previous CTR or previous laryngotracheal reconstruction involving division of the posterior cricoid plate. In CTR, the pathogenesis of arytenoid prolapse may be attributed to division of the lateral cricoarytenoid muscle. In laryngotracheal resection, the pathogenesis of arytenoid prolapse may be attributed to either direct damage to the posterior cricoarytenoid ligament or lateral distraction of the posterior plate of the cricoid.

Arytenoid prolapse is usually managed endoscopically, using a laser to perform a partial arytenoidectomy. The preferred technique is to raise a mucosal flap and debulk the prolapsing cartilage of the arytenoid without damaging the mucosal 'diamond' of the laryngeal inlet. Injudicious use of the laser in the laryngeal inlet predisposes patients to scar formation, fibrosis and narrowing of the supraglottic airway. This, in turn, may induce superimposed supraglottic collapse due to the Bernoulli effect.

Epiglottic petiole prolapse

This presents as a compromised laryngeal inlet owing to the base of the epiglottis (the 'petiole', from the term used to describe the footstalk of a leaf, i.e. the part which connects the blade to the stem) obscuring the anterior true

vocal folds and foreshortening the anterior/posterior diameter of the laryngeal inlet. This problem is most commonly seen in children who have had repeated previous laryngofissure and is a consequence of damage to the thyroepiglottic ligament, where it inserts into the thyroid cartilage just above the anterior commissure. Epiglottic petiole prolapse is rare, and challenging to treat. Injudicious use of a laser in the endolarynx tends to exacerbate the problem, with further scarring narrowing the laryngeal inlet. Suspension of the epiglottic base to the hyoid bone provides some benefit, but is technically challenging and causes the patient significant pain on swallowing for several weeks post-operatively.

Our current management of this challenging problem is to perform a complete laryngofissure and reposition the epiglottic petiole back up to the inner surface of the thyroid ala. The laryngofissure is then closed over a T-tube or suprastomal stent and left in position as a translaryngeal stent for at least 2 months. These patients may have problems with aspiration for some weeks post-operatively.

Acquired anterior glottic webs

Anterior glottic webs are most commonly congenital in origin, and are usually associated with a subglottic extension of the web resulting in coexistent SGS (see Chapter 30, Congenital disorders of the larynx, trachea and bronchi). Acquired anterior glottic webs are less common and are post-traumatic in origin. There are two common aetiologies: anterior neck trauma, often associated with a fractured larynx; and iatrogenic damage, often associated with injudicious use of a laser at the anterior commissure while managing laryngeal papillomatosis. It is rare for prolonged intubation to induce anterior glottic stenosis unless there is also associated SGS.

The management of acquired anterior glottic stenosis differs significantly from the management of the congenital anterior glottic web. The latter has normal mucosa within the remaining glottic inlet, and during reconstruction there may be sufficient mobility of the mucosal layer to reconstruct the anterior commissure without requiring the use of a laryngeal keel. In contrast, acquired anterior glottic stenosis is, by definition, associated with fibrosis and scarring. As such, during reconstruction, following laryngofissure, the mucosa is fibrotic and not amenable to reconstruction of the anterior commissure. Therefore, reconstruction with placement of a laryngeal keel is mandatory while the raw surfaces on either side of the laryngofissure remucosalize.

The usual technique for repair of an acquired anterior glottic web is an open approach with complete laryngofissure, and it is recommended that this is performed with endoscopic guidance. With the laryngofissure complete, the demucosalized raw scar of the anterior vocal folds is noted and, in some cases, there may be enough mucosal mobility to place a pexing suture from the cut edge of the mucosa on either side towards the thyroid ala. Unlike repair of congenital anterior glottic webs, it is unusual to be able to pex the mucosal edge up to the anterior commissure — hence the need for a laryngeal keel. An appropriate size laryngeal keel, such as the Montgomery Keel,™ is then selected and trimmed. The vertical limb of the keel should not impinge into the posterior commissure. The vertical height of the keel should separate the raw surfaces of the laryngofissure. The upper limit of the keel should not be so high as to disrupt the insertion of the epiglottic petiole.

The keel is then sewn into place and the laryngofissure closed. This procedure is normally performed as a two-stage procedure, although a single-stage procedure may be performed with the patient intubated and with the endotracheal tube lying on one side of the vertical limb of the keel. In some children, there is an associated component of SGS, and a decision should be made as to whether the cricoid can be closed adequately over an age-appropriate endotracheal tube. If this is possible, the lower end of the keel should not extend beyond the cricothyroid membrane. If it is not possible, an anterior cartilage graft is placed in the anterior cricoid, distal to the keel.

The keel is removed through an open approach between 10 days and 4 weeks post-operatively. The resultant midline deficit in the thyroid ala is then closed with laterally placed mattress sutures, as the cartilage edges of the laryngofissure are friable and easily damaged if sutures pull out. For this reason, antibiotic coverage and antireflux measures are advised during the period that the keel is in place, and for an additional few days after keel removal.

Endoscopic placement of the laryngeal keel is increasingly a consideration. Even in younger children, it is possible to suspend the larynx on a laryngoscope and endoscopically divide the web with a sickle knife or a laser. The keel may be fashioned from a thin piece of silastic sheeting, with a central suture orientated in the anterior midline across the divided web, and with the silastic sheet placed like the leaves of a book over the divided mucosa. The suture may be placed as an ‘inside-out’ technique using a Lichtenberger needle driver or as an ‘outside-in’ technique using a Keith needle and hollow angiocath.

Posterior glottic stenosis

Posterior glottic stenosis is frequently misdiagnosed and often confused with bilateral true vocal cord paralysis. It may exist as an isolated entity or in combination with SGS. The most frequent aetiology of this condition is prolonged intubation, with the older child being at greater risk than the neonate. The posterior glottis is also susceptible to damage from thermal injury caused by inhalational or airway fires or to iatrogenic damage from use of the laser in the posterior commissure. Occasionally, posterior glottic stenosis may be a result of direct laryngeal trauma.

If not already tracheotomy-dependent, patients present with stridor and exertional dyspnoea. Normal vocal function is usually preserved and, in this regard, presenting symptomatology is similar to that seen in bilateral vocal cord paralysis or cricoarytenoid joint fixation.

Definitive diagnosis requires assessment with rigid bronchoscopy, which confirms the presence of posterior glottic scarring, as a rigid telescope provides excellent visualization of the posterior glottis. Posterior glottic stenosis can, however, be misdiagnosed on bronchoscopy if the telescope is passed directly through the vocal folds to evaluate the subglottis without proactive inspection of the posterior glottis. Bronchoscopic evaluation should also include assessment of the subglottis, which is frequently involved with scarring. An assessment of arytenoid mobility is required as cricoarytenoid joint fixation is an occasional co-pathology. Formal sizing of the airway utilizing endotracheal tubes may be misleading. Posterior glottic stenosis may limit the size of the endotracheal tube that may be inserted. In some cases, however, the vocal folds easily bow laterally to accommodate an age-appropriate endotracheal tube despite still being tethered posteriorly, compromising the airway. It should again be emphasized that the Myer–Cotton grading system is only applicable to SGS.

While flexible bronchoscopy provides a poor view of the posterior glottis and is an inadequate method of diagnosing posterior glottic stenosis, awake flexible nasopharyngoscopy may be extremely useful in determining if vocal fold function is intact. The usual finding is that the vocal folds are mobile but tethered and unable to abduct.

The differential diagnosis for posterior glottic stenosis commonly includes SGS (which frequently may also be present), an interarytenoid scar band, and cricoarytenoid joint fixation. In children referred for the management of posterior glottic stenosis, it is rare to find vocal cord paralysis. By contrast, children referred for the management of bilateral vocal cord paralysis may, in fact, have posterior glottic stenosis tethering the vocal cords and masquerading as vocal cord paralysis. Bilateral vocal cord paralysis and posterior glottic stenosis rarely coexist.

Placement of a posterior costal chondral graft is the mainstay of management and is a highly effective way of achieving an adequate glottic airway.[15, 16] This procedure is best performed through an anterior approach, traditionally through a complete laryngofissure. This approach allows excellent exposure of the posterior glottis and direct visualization of the posterior glottic scar band. The posterior glottis is then infiltrated with 1% Xylocaine with adrenaline. The needle is guided through the posterior plate of the cricoid in the midline until it can be felt to pop through into the space between the posterior cricoid and the oesophagus. A further small amount of Xylocaine and adrenaline may then be injected in two or three positions down the cricoid. This has the advantage of providing not only haemostasis in the postcricoid region but also an additional buffer zone between the posterior cricoid plate and the oesophagus. The posterior cricoid can then be split vertically for its entire length, ensuring that the incision is kept completely in the midline. It is important that the interarytenoid scar band is completely divided. The incision may be continued superiorly through the interarytenoid muscles (which are frequently fibrosed) up to the level of the interarytenoid mucosa itself. Care must be taken not to inadvertently form a posterior laryngeal cleft. Following the posterior split, the cricoid should be easily distracted laterally. A costal cartilage graft is then harvested and carved so that its height is approximately the height of the cricoid split and its depth allows the graft perichondrium to lie reasonably flush with the cut mucosa of the posterior cricoid. The graft may be sewn in place with 4.0 Monocryl™ sutures on a P2 needle. An alternative approach is to form a flanged graft that can be snapped into place and stabilized with a small amount of fibrin tissue glue. With the posterior graft in place, the laryngofissure is then closed over an age-approximate endotracheal tube. If the cricoid does not easily close anteriorly, a further segment of costal cartilage is used as an anterior cricoid graft. A posterior graft rarely needs to be more than 6 mm wide as the primary aim of surgery is to incise the scar tissue and hold the raw edges apart while healing takes place. A graft surpassing this width carries an increased risk of aspiration and a poor vocal outcome.

It is possible to perform this procedure without performing a complete laryngofissure. If the anterior airway incision is carried up to the true vocal cords but not through them, there is usually sufficient access to perform a safe posterior cricoid split and allow insertion of a flanged graft. Such a graft is required, as there is not adequate access to comfortably place sutures with this technique. This technique can even be used in small children.

Posterior cricoid grafting may be performed as a single- or two-stage procedure. Other variations of open reconstruction include scar excision alone, buccal mucosal grafting and a posterior cricoid split without graft placement. However, a posterior split without a graft normally requires a considerable period of stenting before full stability is achieved. A posterior cricoid split without graft placement is most effective in children younger than 9 months of age, and even then, in a single stage procedure, usually requires a 10-day period of intubation.

A posterior costal cartilage graft may be placed endoscopically,[17] and this approach has become increasingly popular over the last 10 years. Patient selection requires no anterior component of SGS, and a larynx that can be adequately exposed. The posterior cricoid may be split with a laser of a sickle knife, and balloon dilation may be used to distract the posterior split. Pockets are created behind the posterior plate of the cricoid to accommodate the posterior flanges of the graft. Significant force is required to place the graft, and balloon dilation may assist with graft placement. This technique may be used to expand the posterior cricoid in posterior glottis stenosis, SGS, or bilateral vocal cord paralysis.

Other endoscopic techniques may also be efficacious; however, they are generally not as reliable as the open approach. Although a laser posterior cordotomy with or without partial arytenoidectomy is effective, there is a significant chance of restenosis. In order to prevent restenosis, the use of mitomycin C is a consideration, as well as placement of a temporary transglottic stent. Other described techniques for the endoscopic management of

posterior glottic stenosis include mucosal advancement flaps, microtrap-door flaps, vocal cord lateralization, and botulinus toxin (Botox) injections.

Whether reconstruction is open or endoscopic, there is a restenosis rate of 10–20%. This rate is higher in children who have had thermal injury to the posterior glottic stenosis. If a child has failed an endoscopic procedure, then open reconstruction is appropriate. Conversely, if a child has failed an open procedure, endoscopic management may be appropriate. In a recalcitrant airway, it is possible to place a second posterior costal cartilage graft if required.

Posterior glottic stenosis

Interarytenoid adhesion is a distinct variant of posterior glottic stenosis, with presentation similar to this condition or to bilateral true vocal cord paralysis. An interarytenoid adhesion results from prolonged intubation, when tongues of granulation tissue lying anterior to the endotracheal tube in the region of the vocal process unite in the midline to form a fibrous scar band. While this usually progresses to form posterior glottic stenosis, mucosal sparing of the posterior commissure sometimes occurs, resulting in the formation of an interarytenoid scar band (**Figure 31.7**). Endoscopic evaluation confirms a small posterior commissure air passage and a larger anterior glottic airway passage. However, there may be a marked limitation to the size of endotracheal tube that can be used for intubation if there is not a tracheotomy tube already present. Endoscopic resolution of this problem is simple and effective. In most cases, microlaryngeal scissors are used to excise the scar band, with immediate resolution of symptoms. In some children, this problem may coexist with either or posterior glottic stenosis.

Subglottic reconstruction

REPAIR TECHNIQUES

Anterior cricoid split

In the neonate who has failed extubation, the anterior cricoid split procedure is an alternative to tracheotomy (**Figure 31.8**). The criteria for anterior cricoid split are specified below:[18]

- failed extubation on at least two occasions
- weight >1500 g
- extubation failure secondary to laryngeal pathology
- no assisted ventilation for 10 days before evaluation
- supplemental O_2 requirement <35%
- no congestive heart failure for 1 month prior to evaluation
- no acute upper or lower respiratory tract infection at the time of evaluation
- no antihypertensive medication for 10 days before evaluation.

The procedure involves an anterior incision of the trachea from the second tracheal ring, up through the cricoid and into the lower third of the thyroid cartilage, just

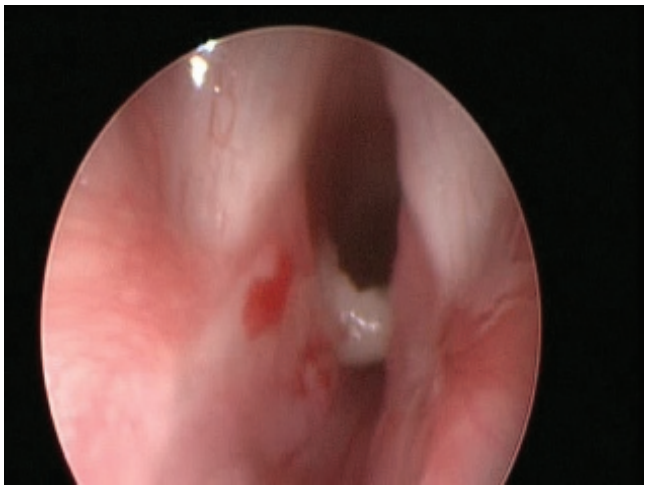

Figure 31.7 Interarytenoid scar band resulting from intubation trauma.

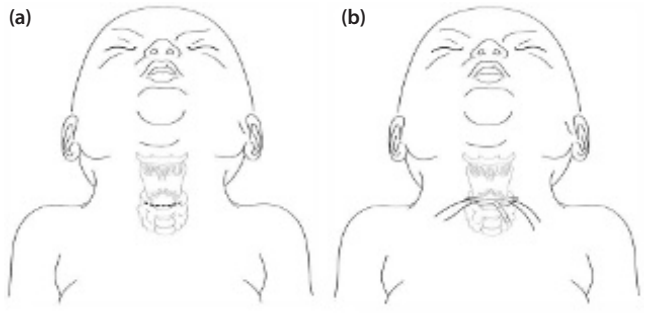

Figure 31.8 The anterior cricoid split procedure.

below the insertion of the anterior commissure. The child is then left intubated for 10 days, with the neck wound left at least partly open to minimize the risk of subcutaneous air build-up. A thyroid alar interposition graft is a modification that permits earlier extubation. It should be noted that while the success rates for this procedure were impressive in initial series, this rate has dropped over time, reflecting advances in neonatal care. Infants who failed extubation 30 years ago are no longer intubated due to the introduction of nasopharyngeal CPAP and high-flow nasal cannulae. Currently, infants requiring intubation and subsequently failing extubation are far more likely to be affected by extreme prematurity or to have other genetic or congenital comorbidities and, as a consequence, success rates for the anterior cricoid split are significantly lower.

Laryngotracheal reconstruction: anterior cartilage graft

Mild to moderate SGS is well managed with costal cartilage grafting to the anterior cricoid (see **Figure 31.3**).[19] The anterior airway is split from the tracheotomy site to the lower aspect of the thyroid cartilage. An age-appropriate sized endotracheal tube or suprastomal stent is then inserted, and a measurement is taken of the size of graft needed to comfortably close the deficit in the anterior airway. A costal cartilage graft is then harvested and carved

to allow a boat-shaped and perichondrium-lined insert to distract the anterior cricoid. An outer flange prevents graft prolapse into the airway. This technique is also useful for managing suprastomal collapse or narrowing of the upper trachea.

Laryngotracheal reconstruction: posterior cartilage graft

Costal cartilage grafting of the posterior cricoid for SGS may be performed in an identical fashion as for posterior glottic stenosis. If the anterior cricoid can then close comfortably over an appropriate sized endotracheal tube or stent, the additional anterior grafting is not required.

Laryngotracheal reconstruction: anterior and posterior cartilage grafts

If the anterior cricoid cannot comfortably close over an appropriately sized endotracheal tube or stent, then an additional anterior graft is required, as previously described. This is necessary for most grade III and all grade IV stenoses.

Cricotracheal resection

Cricotracheal resection (CTR) has an increasing role in the management of SGS. This procedure requires the removal of the subglottic scar tissue, with the anastomosis of healthy trachea to a healthy larynx. This is a technically more challenging operation than laryngotracheal reconstruction with cartilage grafts (**Figure 31.9**).

The success of CTR in infants and children has been documented in large series of patients in three separate centers.[20–22] The results reported are superior to those of the laryngotracheal reconstruction procedures for similar indications and stenosis grades. CTR with primary anastomosis is a safe and effective procedure for the treatment of severe SGS in infants and children. Diagnostic precision is essential, operative timing should be judged carefully, and operative technique must be precise. The reasons for the high success rate include the complete resection of the stenotic segment with restoration of a lumen using a normal tracheal ring, the preservation of normal laryngotracheal support structures without disruption of the cartilaginous framework, and full mucosal lining on both sides of the anastomosis, thus minimizing or preventing granulation tissue and restenosis.

The possible complications of the surgery, however, should not be underestimated. The first is injury to the recurrent laryngeal nerve. Typically, this nerve is not identified during the procedure as it lies posterior to the cricothyroid joint and the resection margin is anterior to the cricothyroid joint. The second complication is dehiscence of the anastomosis. This is most likely to happen if the operative site gets infected or if there is tension at the site of the anastomosis, or because of forceful reintubation if the endotracheal tube becomes dislodged. In the paediatric larynx, the technique of laryngeal release is not required in most cases of CTR. If mobilization of the trachea is difficult or tracheal resection is extensive (more than five tracheal rings), laryngeal release should be performed to minimize the risk of dehiscence. If granulation tissue is allowed to grow, there is also a risk of restenosis. For this reason, sutures through the cartilage should emerge submucosally at the edge of the anastomosis.

Experimental data in primates show that when CTR and primary tracheal anastomosis are performed with a good initial result, the thyroid cartilage and tracheal ring sutured together continue to grow normally. A further advantage of the CTR technique may be that voice quality should not deteriorate because the anterior commissure of the larynx is maintained in its initial position and there is no widening of the larynx posteriorly with an interposition graft. However, in older children, CTR may limit the ability to tilt the thyroid cartilage on the cricoid cartilage, in turn restricting cord tensioning and leading to a loss of vocal range.

Slide tracheoplasty

The slide tracheoplasty was originally conceived as an operation to expand a congenitally stenotic trachea due to complete tracheal rings[23] and is currently the operation of choice for the management of complete tracheal rings.[24] It is a versatile operation and may also be employed for patients with acquired laryngotracheal stenosis. Although originally described using an intrathoracic approach, a cervical approach allows access to the upper two-thirds of the trachea.[25] For patients with combined disease, if the associated SGS makes a graft to the anterior cricoid an option, then the lower trachea may be slid into the split anterior cricoid as an alternative to a costal cartilage graft.

The technique involves adequate exposure of the larynx and trachea, with the stenotic segment then being delineated by an assistant performing bronchoscopy (rigid or flexible) while the surgeon places a 30G needle into the airway. The proximal and distal aspects of the stenosis are marked on the anterior airway, and the length of the stenosis is measured. The trachea is then transected, typically with a bevelled transection commencing on the anterior trachea proximal to the midpoint of the stenosis, and extending over two rings distally, with the posterior transection point being at or just distal to the midpoint of the stenosis. The distal trachea is then split in the midline posteriorly to just beyond the stenosis, while the proximal trachea is split anteriorly to just beyond the stenosis – typically to thyroid cartilage. The most damaged and stenotic segment of trachea tends to lie at the midpoint of the stenosis, and this may be resected if desired. The trachea is then anastomosed with a double-armed PDS suture, typically a 4.0, with RB-1 needles in an older child or adult. A running suture technique is employed, with no attempt to keep the suture extraluminal but with care taken to tighten the running suture as the anastomosis is completed. A single proximal anterior knot completes the anastomosis. The airway is leak-tested and then sealed with fibrin glue, and the patient is typically extubated at the end of the procedure. While it is feasible to perform a slide tracheoplasty into the posterior cricoid, it is technically challenging, and the results are unpredictable. Because of this, it is not recommended.

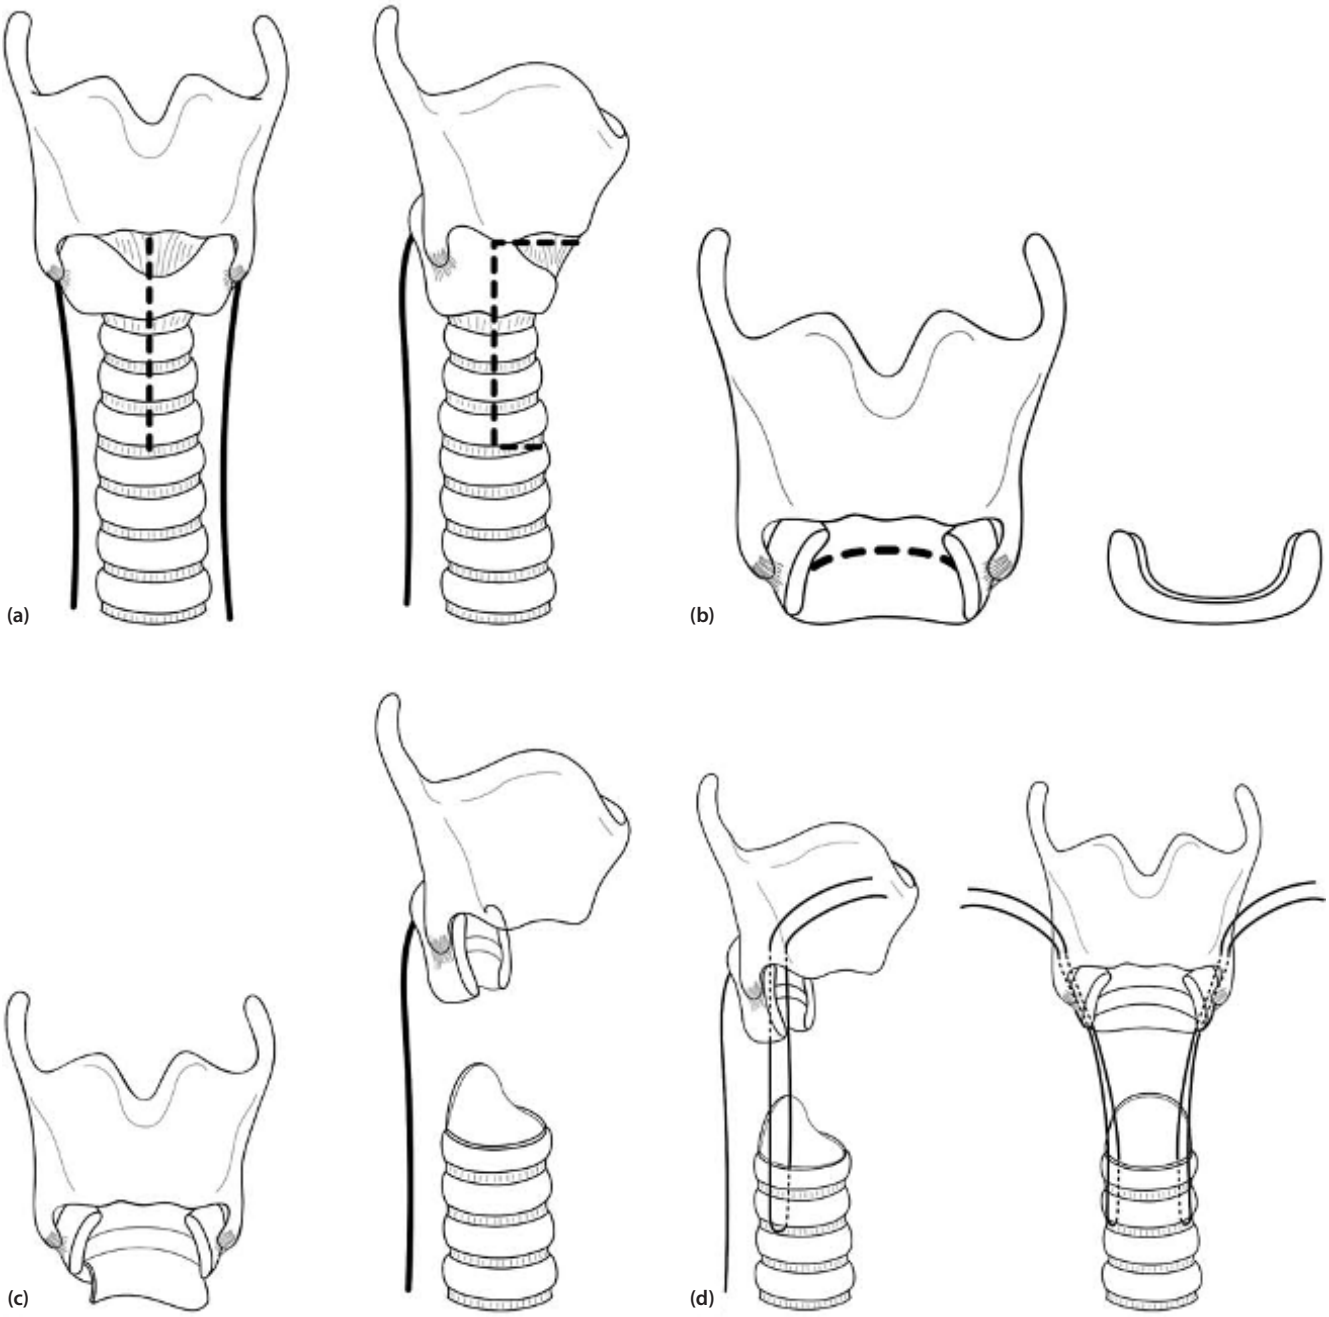

Figure 31.9 Cricotracheal resection.

(Continued)

CONTRAINDICATIONS

All contraindications to airway reconstruction are relative. Usually, airway reconstruction is not attempted unless decannulation is the goal. Gastro-oesophageal reflux disease and eosinophilic oesophagitis should be controlled pre-operatively, and pulmonary function optimized. Operating on a child requiring pulmonary pressure support to ventilate adequately is unwise. Single-stage reconstruction is inadvisable in a child who is difficult to intubate. In children with a history of sedation problems, past failure of airway reconstruction or multiple levels of airway pathology, single-stage reconstruction should be approached with caution. In children undergoing CTR, the risk of anastomotic dehiscence seems higher in the presence of Down syndrome, MRSA or a past history of distal tracheal surgery. The greatest disservice to a child is for airway reconstruction to cause or exacerbate ongoing aspiration.

COMPLICATIONS

Complications may be subdivided into intra-operative, early post-operative and late post-operative.[26] Intra-operative complications include bleeding, pneumothorax

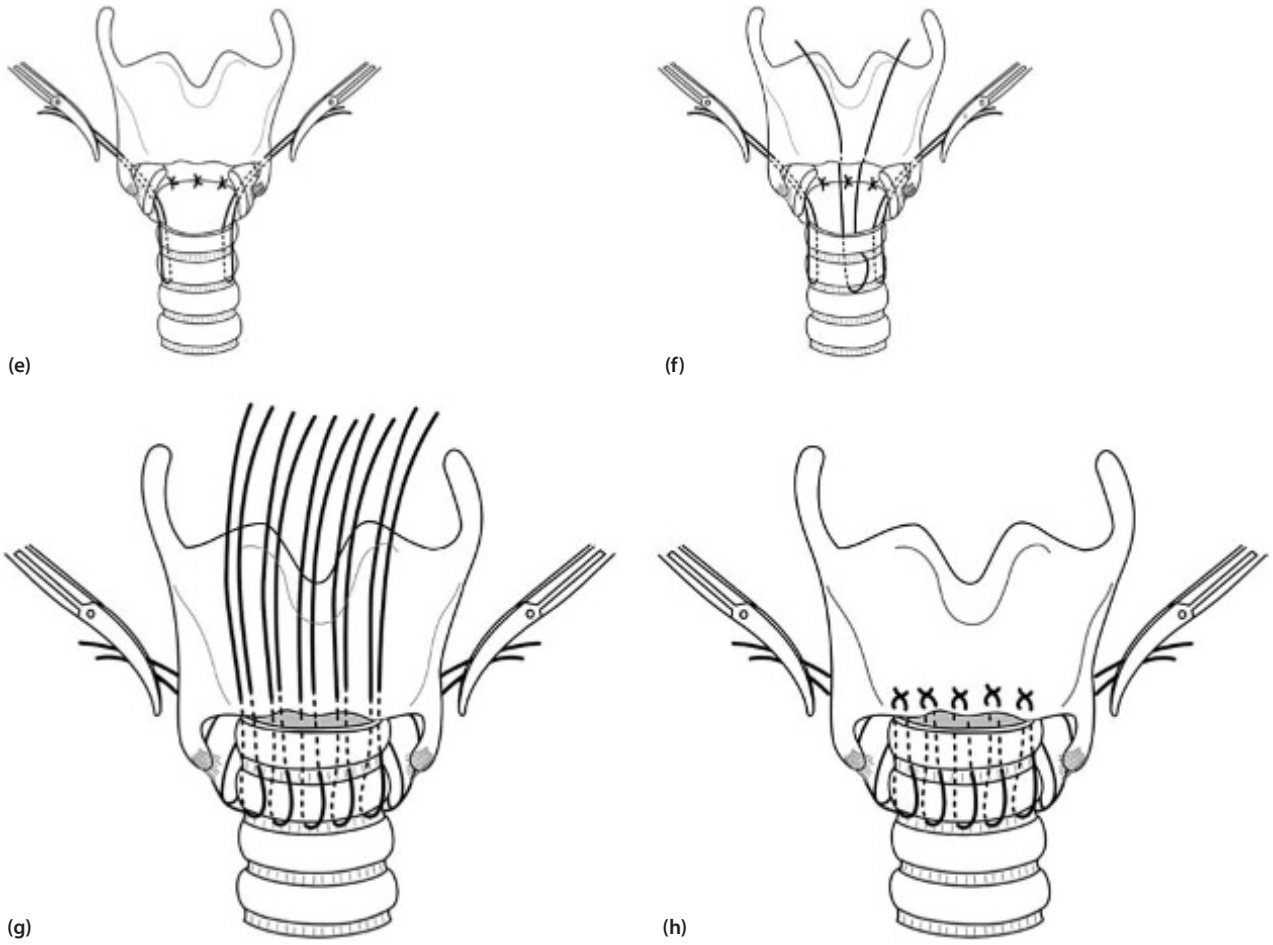

Figure 31.9 (Continued) Cricotracheal resection.

and loss of the airway with resultant hypoxia. Early post-operative complications include infection, air leakage from the operative site, dehiscence of an anastomosis and loss of a graft. The risk of air leakage and graft loss is highest when systemic steroid use is continued beyond two or three peri-extubation doses. With single-stage procedures there is a risk of accidental extubation and risks associated with paralysis or sedation. Extubation may be compromised because of glottic oedema and granulation caused by the endotracheal tube (Figure 31.10). The most significant long-term complication is failure of the reconstruction with restenosis of the subglottis, with an incidence between 10% and 20% in most series.

Revision airway surgery/ the recalcitrant airway

Failure of laryngotracheal reconstruction or CTR does not preclude further attempts at reconstruction but it may complicate further reconstructive efforts. In revision airway surgery, particular care should be taken to optimize the outcome by careful pre-operative evaluation of the patient and their airway. Failed expansion cartilage grafting may still be amenable to either further cartilage grafting or resection, while failed resection may still be amenable to further resection or cartilage grafting.

Figure 31.10 Large granulation arising on an anterior costal cartilage graft in the subglottis 3 days after extubation (10 days after surgery).

BEST CLINICAL PRACTICE

- ✓ In the neonate who has failed extubation, the anterior cricoid split procedure is an alternative to tracheotomy.
- ✓ Pre-operative evaluation of gastro-oesophageal reflux should be mandatory in a child with an active larynx or recalcitrant airway stenosis following previous reconstruction.
- ✓ Functional endoscopic evaluation of swallowing can provide valuable information about the risk and mechanism of aspiration as well as the presence or absence of normal laryngeal sensation.
- ✓ In a child who has not been evaluated previously, flexible nasopharyngoscopy with the child awake should be performed prior to rigid endoscopy.
- ✓ In children with significant lung disease, decannulation may be imprudent. Children with progressive neuromuscular disorders, diaphragmatic weakness or central hyperventilation syndrome may not be candidates for decannulation.
- ✓ In a child with a compromised airway who does not have a tracheotomy tube, pre-operative administration of dexamethasone, 0.5 mg/kg up to a maximum of 20 mg, is a prudent precaution.
- ✓ Spontaneous ventilation offers the best dynamic assessment of the airway and is thus recommended.
- ✓ In children in whom a stenting period of less than 2 weeks is anticipated, consider intubation, with the endotracheal tube acting as the stent (see 'Single-stage reconstruction').
- ✓ A prerequisite for single-stage laryngotracheal reconstruction is an excellent ICU in which staff are familiar with the management of airway patients.

FUTURE RESEARCH

- ➤ While laryngotracheal reconstruction and CTR have become accepted management techniques for SGS, supraglottic airway management remains poorly understood and managed.
- ➤ Pre-operative evaluation and optimization of patients prior to reconstructive airway surgery still requires refinement.
- ➤ Recent technological advances, such as impedance probe evaluation of gastro-oesophageal reflux, need critical evaluation.
- ➤ Balloon dilation of SGS is an area that would benefit from clinical and animal research to help formulate management guidelines.
- ➤ Paediatric voice research may be an area for future endeavour.
- ➤ An airway grading system that is not limited to just the subglottis needs to be developed.
- ➤ Tissue-engineering techniques may offer alternatives to current methods of airway reconstruction.

KEY POINTS

- The narrowest point in the infant airway is the cricoid ring. The only fixed ring within the airway, it is the most vulnerable point for iatrogenic damage caused by intubation.
- Acquired SGS secondary to prolonged endotracheal intubation remains the most frequent cause of laryngeal stenosis.
- Laryngeal stenosis continues to cause significant morbidity and mortality. The most common primary aim of intervention is decannulation or preventing the need for tracheotomy. In selected patients, voice restoration or provision of a safer airway is the primary consideration, with decannulation a secondary goal.
- Evaluation of the paediatric airway should not be considered a minor procedure, particularly when performed in a child with an unstable airway. Extreme care must be taken not to exacerbate the child's condition.
- Rigid endoscopy remains the gold standard for paediatric airway evaluation.
- SGS may be managed endoscopically in selected cases, with balloon dilation being the most effective tool.
- Laryngeal and upper tracheal reconstruction may be challenging; no single operation can address all types of laryngeal stenosis. It is prudent to evaluate each child on an individual basis.
- The most significant long-term complication of surgery for laryngeal stenosis is failure of the reconstruction with restenosis of the subglottis, with an incidence of 10–20% in most series.
- CTR has an increasing role in the management of subglottic stenosis. CTR is particularly effective as a salvage procedure following failed laryngotracheal reconstruction.
- The greatest disservice to a child is for airway reconstruction to cause or exacerbate ongoing aspiration.

CHAPTER 32

JUVENILE-ONSET RECURRENT RESPIRATORY PAPILLOMATOSIS

Rania Mehanna and Michael Kuo

SEARCH STRATEGY

Data in this chapter may be updated by a PubMed (NLM) search using the keywords: respiratory papillomatosis and laryngeal papillomatosis.

INTRODUCTION

Recurrent respiratory papillomatosis (RRP) is a potentially life-threatening disease characterized by the development of papillomata anywhere in the respiratory tract from the nasal vestibules to the terminal bronchi. Predominant sites are where there is a change of epithelium (e.g. from squamous to ciliated) and especially the tonsillar pillars, uvula, vocal folds and laryngeal commissure. There is a bimodal age distribution with a juvenile-onset peak occurring at 3–4 years of age and an adult-onset peak occurring at 20–30 years of age. A younger age at onset tends to reflect more aggressive disease. Boys and girls appear to be nearly equally affected in juvenile-onset RRP (JORRP). This contrasts with adult-onset RRP, which is a disease transmitted via sexual contact or via indirect contact with anogenital lesions, preferentially affecting men by a ratio of approximately 3:2. Although adult-onset respiratory papillomatosis and juvenile-onset respiratory papillomatosis share many features, this chapter addresses only JORRP.

AETIOLOGY

Juvenile respiratory papillomatosis was first described by Morrell Mackenzie in 1880. By 1923, Ullmann had demonstrated an infective aetiology by injecting homogenized papilloma from a child's larynx into his own forearm and inducing local growth of papillomas. Further direct evidence of the association between human papilloma virus (HPV) and RRP came from the identification of HPV DNA within laryngeal papillomas by Southern blot hybridization and the subsequent recognition in papillomas of HPV types 6 and 11.[1] Human papillomavirus is a naked, double-stranded, icosahedrally shaped virus with circular supercoiled double-stranded DNA genome surrounded by an outer capsid of protein that belongs to the papovavirus family. There are over 200 known subtypes of HPV – although many vary only slightly in their DNA sequence – but only types 6, 11 and rarely 16 are associated with RRP, with HPV 11 conferring a more aggressive course than HPV 6.[2] HPV types 6 and 11 are also associated with condyloma acuminata (genital warts). Types 16 and 18 have been implicated in carcinogenesis, particularly in the uterine cervix and in squamous cell carcinoma of the head and neck. HPV is thought to first enter traumatized epithelium and reside in the basal layer of the mucous membrane, where it replicates by a process known as episomal maintenance. This replication interferes with the normal process of cell maturation, causing epithelial proliferation and neovascularization. Conversely, the virus may lie dormant, causing subclinical infection, and can often be recovered from apparently normal tissue adjacent to papillomas. Viral protein, DNA synthesis and virion assembly only takes place in the granular and cornified layers of the terminally differentiated epithelium.

EPIDEMIOLOGY

Juvenile-onset RRP is an uncommon condition, with a prevalence of only 4 in 100 000 children. The oft-quoted triad of susceptibility factors for JORRP – young mother, vaginal delivery and low maternal socioeconomic status – is of limited predictive usefulness.[3] Latent or active HPV has been detected in cervical swabs from 10–25% of women of childbearing age. The associations between HPV, JORRP and a history of maternal genital warts are well established but what is uncertain is the influence, if any, these associations should have on obstetric management. HPV DNA has been found in one-third to one-half of aerodigestive tract swabs of children born to affected mothers. However, the majority of these children do not develop disease. Calculations suggest that only 1 in 400 infants delivered to women with genital warts subsequently develops JORRP. This relative risk is much lower than that for sexually transmitted diseases.

Although a history of maternal genital warts is not universal, a large retrospective study has shown that children born to mothers with genital warts carry a 231× relative risk of developing JORRP. A prolonged delivery time (exceeding 10 hours) conferred a twofold increased risk but delivery by Caesarean section did not appear to reduce that risk.[4] The clinical corollary of this is whether elective Caesarean section should be recommended for subsequent deliveries when one child has RRP. The overwhelming majority of children born to women with HPV do not develop RRP. In addition, many individuals with HPV in the tissues of the respiratory tract never develop papillomas. Additional host factors, such as immunological or genetic ones, determine the development of RRP in individuals with HPV. Other factors such as timing, length and volume of exposure to the HPV also play a role.[5] The evidence for protection from vertical transmission of HPV into the baby's upper respiratory tract by Caesarean section is conflicting and therefore the decision on method of delivery must be made on a case-by-case basis. Current evidence does not warrant Caesarean section as a prophylaxis against RRP.

Variation in the susceptibility of the host to viral infection may be associated with specific HLA polymorphisms, several of which have been reported. Two recent, large independent studies have shown an association between HLA-DRB1*0301 and severe disease.[6, 7] T-cell responses were shown to be the same by one group between HLA-DRB1*0301-positive patients and negative controls, leading to speculation that the clinical severity of disease is due not to a failure of T-cell proliferative response to HPV but a delay in that response due to a low frequency of HPV-specific T cells or modulation of the T-cell response by immunoregulatory networks.[7] Bonagura et al.[6] showed that HLA-DRB1*0301-positive patients exhibited reduced interferon-gamma expression. While the associations between JORRP and HLA-genotype are being increasingly well recognized, the underlying mechanism for evasion of the cellular immune response is far from clear.

CLINICAL PRESENTATION

Although respiratory papillomas can arise in any respiratory mucosa, their initial presentation is usually in the larynx. The diagnosis requires the surgeon to have an awareness of the condition as the presenting symptoms can be variable and mimic many common laryngeal and respiratory pathologies in children. In addition to hoarseness and stridor, children may present with a chronic cough, paroxysms of choking, recurrent respiratory infections or failure to thrive. These latter symptoms may lead to a misdiagnosis of asthma, laryngitis, bronchitis or croup and a delay of diagnosis of JORRP of up to 8 years.[1]

DIAGNOSIS

If at all possible, the clinical diagnosis should be established with awake fibre-optic nasolaryngoscopy (using an infant 2.2 mm or 2.7 mm endoscope) because the difficulties presented to the anaesthetist by unexpected laryngeal papillomas prolapsing into and obstructing the glottis cannot be overstated.[8–10] The preferred anaesthetic technique in our institutions is that of spontaneous respiration without endotracheal intubation. General anaesthesia is induced either by intravenous propofol or, more frequently, by inhalation of sevoflurane in oxygen. The larynx is topically anaesthetized with 2% lidocaine and anaesthesia maintained by sevoflurane in oxygen through a nasopharyngeal airway, of a size and length appropriate for the child's age. This allows excellent surgical access to the airway but carries the disadvantage that the lower airway is not directly protected from bleeding. Meticulous haemostasis is therefore required during the procedure using topical epinephrine (1:10 000 applied on neurosurgical patties). Regardless of the surgical technique, it is important for the child to recover from anaesthesia with humidified oxygen. Many units use pre-operative dexamethasone to reduce laryngeal oedema but some surgeons feel that anti-inflammatory agents are best avoided during active manipulation of papilloma tissue. Laryngopharyngeal exposure to gastric acid is increasingly being recognized as a cause of laryngeal pathology. This is particularly relevant during the immediate post-operative period where laryngeal mucosa has been breached.[11] Therefore it is our practice to give prophylaxis against gastro-oesophageal reflux with an H_2-antagonist or a proton pump inhibitor for 48 hours after all laryngeal surgery, including surgery for JORRP.

Macroscopically, papillomas can be pedunculated or sessile, spread over the mucosal surface of the larynx (**Figure 32.1**). They tend not to be friable and can be grasped using microlaryngeal instruments and excised for histological examination. Microscopically, the papillomas appear as exophytic projections of keratinized squamous epithelium overlying a fibrovascular core, with varying degrees of dyskeratosis, parakeratosis and dysplasia. Koilocytes (vacuolated cells with clear cytoplasmic inclusions) are often seen indicating viral infection.

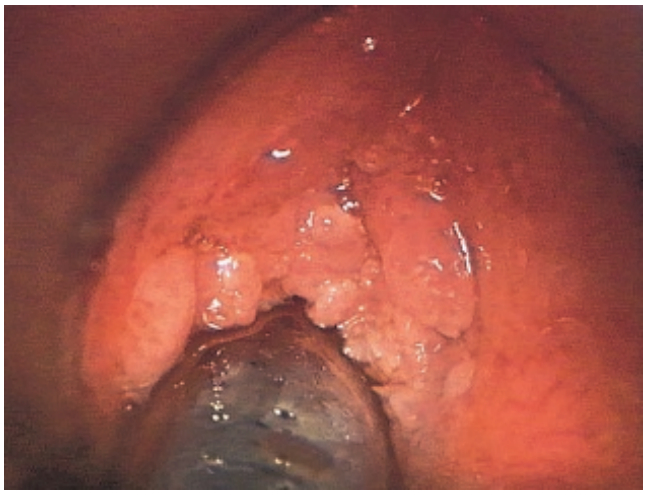

Figure 32.1 Recurrent respiratory papillomatosis in the larynx.

STAGING

Staging of disease is not universally undertaken even in units with a large caseload of RRP. The staging system proposed and modified by Derkay (Figure 32.2)[12, 13] is based on a combination of the anatomical distribution and extent of lesions and their clinical effects on voice and the child's airway. It is increasingly used by members of the American Society of Pediatric Otolaryngologists (ASPO). Widespread adoption of a universally agreed staging system would enable comparison of results between centres and facilitate multicentre trials, particularly of adjuvant treatments.

For each site, score as:
0 = none, 1 = surface lesion, 2 = raised lesion, 3 = bulky lesion

Larynx	
Epiglottis:	Lingual surface _____
	Laryngeal surface _____
Aryepiglottic folds:	Right _____ left _____
False vocal folds:	Right _____ left _____
True vocal folds:	Right _____ left _____
Arytenoids:	Right _____ left _____
Anterior commissure	_____
Posterior commissure	_____
Subglottis	_____
Trachea	
Upper one third	_____
Middle one third	_____

TREATMENT

The aim of surgical treatment is the removal of papillomas and restoration of a safe and patent airway while minimizing trauma to the mucosa and vocal cords. Risk of scarring and webbing can be reduced by the avoidance of two opposing raw surfaces, especially at the anterior commissure. In children requiring repeated extirpations of extensive papillomas, especially if they predominantly occur in the larynx, it may be ultimately impossible to achieve normal voice. Though the papillomas do not extend beyond the basement membrane, there is often inevitable inadvertent damage to surrounding tissues.[14] It is in these patients that the surgical technique, balance of the extent of lesion removal against interval timing, and application of adjuvant therapies must be combined and finely judged to ensure minimal dysphonia and airway stenosis, both of which can be extremely difficult to manage. No single treatment modality is better than another. The heterogeneity of the disease and its natural history is reflected in one series of 118 patients who underwent surgical management for their JORRP; the total number of operations per patient ranged from 2 to 402.[15]

Surgical treatment

POWERED MICRODEBRIDER

The use of the powered microdebrider is a relatively new development in the surgical removal of laryngeal papillomas, but one which has become the gold standard for papilloma removal in the larynx (Figure 32.3).[16] A non-serrated laryngeal blade is used with a setting of 300–700 rpm which allows the papillomas to be suctioned into the debrider with minimal cutting trauma to surrounding normal tissues. The laryngeal debrider blade allows gentle but comprehensive removal of papillomas with minimal contamination of the lower respiratory tract with blood or papillomas. There is no thermal trauma and, using direct endoscopic control, it is extremely precise with minimal mucosal damage. Small retrospective studies demonstrate that, compared with the CO_2 laser, patients undergoing laryngeal papilloma debridement have good disease clearance, require a shorter procedure and experience less post-operative pain. One retrospective study showed no incidence of delayed soft-tissue complications using the microdebrider.[17–20]

COLD STEEL SURGERY

Advocates of papilloma removal using microlaryngeal instruments claim that the use of a microflap technique minimizes trauma to the vocal fold while satisfying disease clearance. Thermal damage to neighbouring tissue is also avoided, as is the vapour plume. Cold steel surgery has

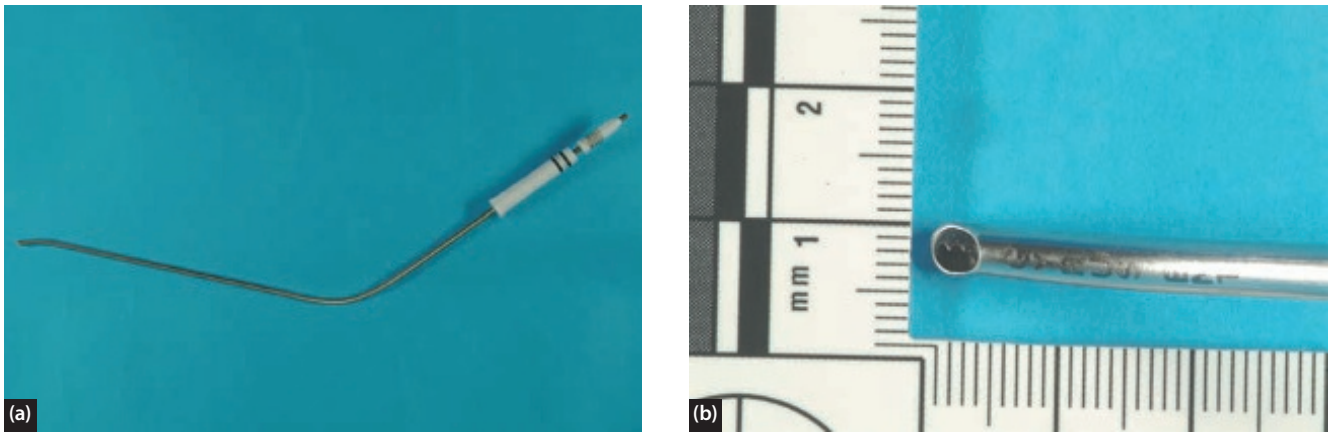

Figure 32.3 (a) Microdebrider; **(b)** close-up of blade.

the distinct disadvantage of having no direct haemostasis when dealing with a very vascular lesion. Nevertheless, such surgery is successful in the hands of the exponents of this technique.

CO_2, KTP, ND:YAG AND PULSED DYE-LASER

The carbon dioxide (CO_2) laser has been, for many years, the mainstay of surgical management of JORRP. It remains the treatment of choice for many surgeons because of its ability to ablate the papillomas with minimal bleeding and its ease of use with a microscope and micromanipulator. However, the frequency of late soft-tissue complications, such as vocal fold fibrosis, interarytenoid fibrosis and stenosis, glottic webbing and arytenoid fixation, has been reported to be 13–45%.[8, 21, 22] This increases with frequency of treatment and the number of laser ablations the child has received. Soft-tissue complications can be minimized by appropriate laser settings and careful assessment of depth of ablation. A Japanese group has suggested, based upon a single case, a two-stage procedure whereby the bulk of the papillomas are removed at the first operation, which is then followed by a repeat endoscopy and laser ablation 10 days later, by which time the coagulum and carbonized tissue have resolved, allowing a more precise laser clearance of residual papillomas.[23] It is also important to have an effective plume extractor. This serves to allow a clearer image of the larynx, but also removes the potentially infectious laser vapour plume which carries a significant viral load. The latter may be simple conjecture as there has only been one reported case of a surgeon developing laryngeal papillomas with a history of repeated laser treatment to a patient with anogenital condylomas, *in situ* hybridization showing HPV types 6 and 11 in both the patient's and his lesions.[24]

The KTP laser and the Nd:YAG laser are as effective as the CO_2 laser in papilloma ablation and haemostasis but, in addition, can be delivered through an optical fibre. Fibre-delivered laser systems play a role predominantly in the treatment of tracheal and bronchial papillomas. A new fibre-guidance system with a bendable distal tip developed for the Nd:YAG laser achieves a 50° range of directional manoeuvrability with minimal power loss.[25] In adult patients, the delivery of pulsed-dye laser through a flexible bronchoscope can render it an outpatient procedure.[26]

The advantages of the pulse-dyed laser are that it can be fibre-delivered and causes minimal vocal-fold fibrosis and consequently minimal voice damage. However, it also distinguishes itself from the other forms of laser treatment in its mode of action. Rather than direct vaporization of tissue, it has been proposed that the 585 nm pulsed-dye laser is a vascular laser which causes photoangiolysis of sublesional microcirculation, denaturation of epithelial basement membrane linking proteins, and cellular destruction.[26] Therefore, it is less effective against large exophytic lesions and can be used as an adjunct to surgery either before or after the laser application.[27] The application of the pulsed-dye laser in the paediatric population is still under evaluation, but the results in adults with recurrent respiratory papillomatosis are very encouraging.

Photodynamic therapy

Photodynamic therapy (PDT) relies upon the observation that rapidly proliferating tissue selectively takes up a number of photosensitizing agents when administered intravenously, and that these agents release tumouricidal oxygen derivatives when activated by laser light of the appropriate wavelength. A non-blinded randomized prospective trial using dihaematoporphyrinether (DHE) at two different doses in combination with 50 J of 630 nm argon laser light was compared with laser treatment alone. The patients remain photosensitive for 6–9 months and may experience skin erythema, blistering and ocular discomfort. Patients on the higher dose of DHE (4.25 mg/kg body weight) were reported to show a significantly larger decrease in papilloma growth rate but, despite that, only approximately half of the 48 patients receiving DHE showed a response, and no response was seen in patients previously treated with PDT.[28] A further randomized trial by the same group using meso-tetra (hydroxyphenyl) chlorin (mTHPC) as a photosensitizer showed reduction of severity of laryngeal papillomas in the mTHPC group, but this was not maintained and there was no effect on tracheal disease.[29] It should be noted that this trial recruited only 23 patients,

of whom only 15 completed the study. In both trials, there was a combination of juvenile-onset and adult-onset patients.

Coblation®

Coblation® is a minimally invasive low-heat technology that delivers a plasma layer to dissolute target tissue while maintaining the integrity of surrounding tissues. The wands (**Figure 32.4**) are designed to function at temperatures as low as 40–70 degrees Celsius (°C), thus minimizing rapid heating, charring or burning. In comparison, commonly used bipolar devices function at temperatures of approximately 400 °C. There are very limited data on the use of Coblation® for JORRP, with most of the literature being case reports or retrospective results on small number of patients.[30, 31] A recent cross-sectional study in the United Kingdom showed that Coblation® procedures accounted for 3% of interventional treatment conducted in the UK RRP population.[32]

Adjuvant therapy

Adjuvant medical therapies can be broadly divided into antiviral therapies and drugs with antiproliferative or immunomodulatory properties.[33–35] The decision to implement adjuvant therapy must depend on a careful consideration of the benefits against potential adverse effects of the therapy.[36] Adjuvant therapies which have been described in isolated case reports have been included for reference because, while their use in 'routine' cases may not be justified, one may wish to consider their use when other better-tested avenues are exhausted.

INTERFERON-α

Interferons are naturally produced by human leucocytes although, as a pharmaceutical, interferon is now produced via recombinant DNA technology. Interferon-α can claim to have antiviral, antiproliferative and immunomodulatory properties. Interferons exert an indirect antiviral action by interfering with normal host cell translation mechanisms and by inducing synthesis of intracellular enzymes that act to control viral growth. By depleting essential metabolites in papilloma cells, interferon-α increases the length of their multiplication cycle, thereby slowing target cell growth. Interferon-α also facilitates recognition of papilloma cells by circulating leucocytes by enhancing expression of cell surface antigens. It is administered systemically by subcutaneous injection at a dose of 2–5 MU/m^2 of body surface area.[37] It is the most well studied of the adjuvant therapies for JORRP. A large randomized trial of 123 patients showed significant reduction in papilloma growth rate within the interferon arm. However, this was only significant for the first 6 months and the difference was not statistically significant during the second 6 months.[37] In another randomized crossover trial of 66 children, there was significant reduction in disease bulk in the interferon arms of the trial.[38] This was extended to longer follow-up, at which data on 60 children were still available, showing complete remission in 22 children, partial remission in 25 patients and no response in 13.[39] The main problem preventing more widespread use of interferon-α is that there are many serious, idiosyncratic and unpredictable side effects including pancytopenia, hepatorenal failure and cardiac dysfunction. There is also a rebound phenomenon associated with withdrawal of the drug therapy. There is anecdotal evidence of the use of intralesional interferon in combination with laser debulking of JORRP, but this has not found widespread use.[40]

Figure 32.4 PROCISE laryngeal Coblation® wand (courtesy of Smith & Nephew).

BEVACIZUMAB

Bevacizumab (Avastin) is a recombinant monoclonal antibody that inhibits angiogenesis (VEGF-A). It is licensed for use in a wide range of metastatic cancers. Trials involving small numbers of patients with recurrent respiratory papillomatosis have shown promise both by systemic and intralesional administration. A series of five patients treated with systemic bevacizumab responded dramatically with 18 surgical interventions being required in the 12 months prior to treatment and only one in the 12 months following treatment.[41] Usually administered at a concentration of 2.5 mg/mL for three consecutive injections at 2–3 week intervals, it can be used in conjunction with cidofovir (see below) and/or the KTP laser. Early studies report an increased time interval between operations, and thus a reduced number of procedures per year. They also report improved voice quality of life when using the Paediatric Voice-related Quality of Life (PVRQOL) score.[42]

CIDOFOVIR

Cidofovir is an acyclic nucleoside phosphonate which is active against a broad spectrum of DNA viruses including cytomegalovirus, Epstein–Barr virus and HPV. Its mechanism of action is by inhibition of viral DNA polymerases essential for viral replication. The principal application of this drug has been in the treatment of cytomegalovirus (CMV) retinitis in human immunodeficiency virus (HIV)-infected patients by intravenous injection. This mode of administration and high doses is associated with neutropenia and nephrotoxicity. Intralesional injection

of cidofovir in JORRP is not associated with similar side effects. A canine model has shown that local irreversible soft-tissue damage could be avoided in twice weekly cidofovir injections if the dose is limited to below 40 mg/mL.[43, 44]

Based on their animal work, Chhetri and Shapiro[45] have proposed a schedule for treatment of JORRP based on intralesional injections of cidofovir at a concentration of 1 mg/mL. Injections were given at 2-weekly intervals for four treatments and then the interval between treatments extended by 1 week after each and every subsequent treatment. Concomitant laser surgery was reserved for bulky lesions. Five patients were treated with this schedule with a mean follow-up time of 66 weeks. The mean papilloma stage decreased from 9.2 at initial presentation to 3.4 within 2 weeks of the first injection, and continued to decrease for the remainder of the follow-up period. After 9 weeks of treatment, no patients required further laser surgery. The authors counsel caution that the potential long-term carcinogenic effects of cidofovir are unknown and a 'response' may be related to the natural history of the disease.[46]

In vitro studies have shown that the use of cidofovir raised the HPV E6 RNA levels by 8-fold in low-risk and 20-fold in high-risk E6 expressing HPV cervical cancer cells.[47] A cross-sectional study incorporating adult and paediatric laryngeal surgeons found that the incidence of upper aerodigestive tract cancers was not significantly increased in patients in whom cidofovir was deployed. Thus, the RRP Task Force recommended that intralesional cidofovir should be considered in patients with RRP that require surgery at less than 3-month intervals, with regular biopsies. Administration should remain below the established safe dose of 3 mg/kg. In all cases, informed consent must be obtained including off-label use and possible side effects.[48] A recent meta-analysis by Fusconi et al.[14] looked at all published data using cidofovir as an adjuvant treatment option for RRP since 1998. It looked not only at the concentration of cidofovir used and the response rate, but also at the incidence of dysplasia secondary to cidofovir injections. There still appears to be no consensus on the ideal dose, frequency of administration and duration of cidofovir treatment. Importantly, there was no evidence that cidofovir promotes evolution towards dysplasia even after cumulative doses.[14]

RIBAVIRIN

Ribavirin is a synthetic nucleoside which has activity against a broad spectrum of viruses, but which is principally used as an aerosol in the treatment of respiratory syncytial virus pneumonia and systemically in the treatment of hepatitis C. There have been reports of its use both as an aerosol and systemically.[49–51] However, these remain anecdotal reports and ribavirin is not widely used as an adjuvant treatment of JORRP.

ACYCLOVIR

The evidence on the efficacy of acyclovir is weak and conflicting.[52, 53] Although HPV is a DNA virus and acyclovir has a medium spectrum of antiviral activity, it does not directly inhibit HPV. Acyclovir is a nucleoside analogue, which inhibits thymidine kinase, which is present in herpes simplex viruses (HSV) but not HPV. Adult patients, but not paediatric patients, with RRP have been shown to have molecular evidence of coinfection with other viruses, particularly HSV, which may have a potentiating effect on HPV. It has been suggested that the mechanism of action of acyclovir is to eradicate HSV, thus removing this synergism. Side effects are rare and include nausea, vomiting, diarrhoea, fatigue and headache.

INDOLE-3-CARBINOL

Indole-3-carbinol is a substance derived from cruciferous vegetables (e.g. cabbage, broccoli, cauliflower, brussels sprouts), which has been shown to alter growth patterns of JORRP cell cultures *in vitro*. It affects oestrogen metabolism, shifting production to antiproliferative oestrogen. A prospective observational study with a mixed adult and paediatric population who received indole-3-carbinol as an adjunctive treatment to surgical removal showed partial or total responses in 21 of 33 patients. Within the paediatric subgroup, four out of nine showed partial or total response with no evident side effects.[54]

CIMETIDINE

Cimetidine – a histamine receptor type 2 (H2) antagonist – has been reported as a useful treatment for cutaneous warts. It has also been successfully used in treatment of an 11-year-old boy who had an 8-year history of diffuse conjunctival papillomas. The mechanism for this is attributed to immunomodulatory side effects of cimetidine at high doses. There is a single case report of very advanced JORRP with tracheobronchial-pulmonary involvement being treated successfully with adjuvant cimetidine at a dose of 40 mg/kg for 4 months with remarkable improvement.[55]

NATURAL HISTORY

The natural history of RRP is extremely variable. This makes it difficult for the surgeon to be able to reliably counsel the anxious parents on how their child's pathology will behave or at what age they might expect remission. Pathologically, severe disease is strongly associated with HPV-11 infection and thus patients should have viral typing as part of their initial pathology workup. Poor prognostic signs include onset of disease before the age of 3 years, and birth by Caesarean section. In the United States, Medicaid insurance – often seen as a proxy measure of low socioeconomic status – is also associated with severe disease.[56] However, there are no other studies showing correlation between socioeconomic status and disease severity. Most affected children require debulking of papillomas at 2–3-month intervals during periods of disease activity. Severe disease may necessitate weekly surgical intervention to prevent

airway obstruction from rapidly growing papillomas. The median number of debulking procedures required in a patient is reported to be 7–13.[57, 58] Not surprisingly, the repeated debulking of laryngeal papillomas results in chronic voice changes.

There is a tendency for remission in the early teenage years and this has been attributed to hormonal changes occurring with the onset of puberty. Interestingly, women with adult-onset RRP commonly experience severe exacerbations of their disease during the hormonal fluctuations of pregnancy. What is clear is that remission is not related to the clearance of HPV from the mucosa as viral DNA is detected in previously affected mucosa in patients in remission as well as in normal mucosa of patients with active disease.[59]

TRACHEOBRONCHIAL DISEASE

Extralaryngeal spread of JORRP beyond the larynx occurs in approximately one third of patients, with spread to the trachea in approximately one quarter of patients. Tracheal involvement may appear as cobble-stoning of the mucosa coupled with the presence of papillomas. Factors predisposing to tracheal spread include the presence of subglottic papillomas, presence of a tracheostomy and a long duration of disease.[60] More distal bronchopulmonary involvement is reported in 4–11% of children with long-standing disease and may result in obstructive pneumonias.[37] Patients may develop cavitary pulmonary lesions leading to fever, sepsis and pulmonary atelectasis. Radiographically, these lesions may appear as solid or cystic pulmonary masses (**Figure 32.5**).[61] A high index of suspicion must be maintained for malignant degeneration of bronchopulmonary lesions.

Figure 32.5 Chest radiograph showing extensive pulmonary involvement with papilloma.

TRACHEOSTOMY

The indications for tracheostomy in patients with JORRP continue to divide clinicians. The source of this debate is that tracheostomy essentially constitutes an iatrogenic squamociliary junction and may present an additional area of predilection for papillomas.[62] There is anecdotal evidence that tracheostomy may promote extensive tracheobronchial 'seeding' of disease. However, it is not universal that all patients with a tracheostomy develop either stomal papillomas or tracheobronchial disease. Tracheostomy is very much a last resort but in patients with severe disease it may be life-saving. It may also facilitate a longer interval between debulking procedures to restore some normality to the child's life.

MALIGNANT DISEASE

Malignant degeneration of papillomas is a rare but devastating sequel. It is universally fatal.[61] There is a higher incidence of invasive carcinoma ex-papilloma in children with a younger age of onset (2 vs 6 years old; $P = 0.009$) and those with tracheal involvement.[63] Irradiation of papillomas dramatically increases the risk of malignant transformation but as this is no longer used as a treatment modality, it is of only historical relevance. Most instances of malignant transformation have been reported in adult patients and have been associated with other risk factors including tobacco use and long-standing disease. Malignant transformation appears to be more likely with HPV 16, an unusual cause of JORRP, but HPV 6 and HPV 11 have been shown to oncogenically transform cell culture lines *in vitro*. In adults, malignant degeneration usually involves the larynx, unlike children where cancer usually develops in the bronchopulmonary tree.

Approximately 20 paediatric cases of malignant degeneration have been reported, all of which have been fatal. The currently proposed mechanism of malignant transformation involves oncoproteins E6 and E7. HPV types 6 and 11 produce transforming oncoproteins E6 and E7 that have been implicated in growth dysregulation through their ability to inactivate the tumour suppressor proteins p53 and the retinoblastoma tumour-suppressor gene product (pRb). The inactivation of the tumour suppressor genes results in a loss of control over proliferation and cell division and contributes to the development of the malignant phenotype. It is also becoming clear that the E6 and E7 proteins function to promote tumorigenesis through direct interactions with cell-cycle regulatory proteins.[64] Unfortunately, apart from closer clinical and radiological surveillance particularly in children with tracheal and/or pulmonary disease, there is little to aid the clinician in predicting the rare cases of malignant transformation.[65] There is no evidence of a papilloma–carcinoma sequence while *p53* overexpression is variable and not a marker of malignant transformation.[64] HPV expression may be lost in malignant transformation but this may not be a sufficiently robust clinicopathological predictor.

VOICE MORBIDITY

Although there are numerous papers on the various treatment on options for JORRP, there are limited data on the vocal outcomes of these patients. The majority of data are based on adult-onset RRP looking at voice both due to the papillomas themselves and the resultant morbidity of multiple surgical procedures. Well-recognized voice assessment scales include the GRBAS (grade, roughness, breathiness, asthenia and strain) scale, the Voice Handicap Index (VHI), Short-Form 36-Item Health Survey (SF-36).[66]

Objective assessment of voice by GRBAS scale and Visi Pitch II 3000 acoustic analysis has shown significant difference between JORRP patients in remission and normal controls, but a Voice-related Quality of Life Questionnaire (V-RQoL) showed that the dysphonia does not have any impact on quality of life.[67]

A high number of surgical procedures correlates with a poorer voice in acoustic analysis using the GRBAS. This was statistically significant for grade. Interestingly, Ilmarinen et al. showed no statistical significance in VHI score. When comparing post-op acoustic voice parameters, patients treated with the microdebrider appeared to have lower scores for jitter, shimmer and perceptual scores, thus indicating a better voice outcome with the microdebrider when compared to the CO_2 laser. Increased frequency of interventions using the CO_2 laser is associated with poorer voice quality.[66, 68]

VACCINATION/PREVENTION

There are currently two HPV vaccines, Cervarix® and Gardasil®. These vaccines contain no live virions and are thus incapable of causing an infection, but they are designed to induce an antibody response. Cervarix® is bivalent vaccine against HPV 16 and 18. Gardasil® is a quadrivalent vaccine against HPV 6, 11, 16 and 18 containing virus-like particles of the L1 protein of the four strains. The vaccination schedule comprises three intramuscular injections: the initial dose, 2 months later, and finally 6 months after the initial injection. More recently, Gardasil® has been enhanced to a nonavalent vaccine (HPV 6, 11, 16, 18, 31, 33, 45, 52 and 58). Ideally, the vaccine should be given to young boys and girls, from the age of 9 years old, prior to them becoming sexually active, thus reducing the spread of HPV and its sequelae in the general population.

Australia was the first nation to introduce a nationwide government-funded vaccination programme in 2007, directed towards the eradication of cervical cancer. Vaccination resulted in a statistically significant decrease in the prevalence of HPV 6, 11, 16 and 18 in cervical samples in the post-vaccination period (2010–2011) as compared to the pre-vaccination period (2005–2007).[69] Much interest has been directed at evaluating the use of HPV vaccination in influencing the clinical course of RRP. Only one study explored this in an entirely juvenile-onset population. There was no change in the clinical or anatomical scores, the number of relapses or the intervals between surgeries before or after vaccination with Gardasil®.[70] Other studies involving juvenile-onset and adult-onset patients have shown more promising results. Albeit involving small numbers of patients, these studies have demonstrated both a clinical and an immunological response to quadrivalent HPV vaccine, suggesting vaccination may have both a preventive and a therapeutic role.[71, 72]

BEST CLINICAL PRACTICE

- ✓ Current evidence does not warrant Caesarean section as a prophylaxis against RRP.
- ✓ Ideally, the clinical diagnosis should be established with awake fibre-optic nasolaryngoscopy prior to general anaesthesia.
- ✓ Patients should have viral typing as part of their initial pathology workup.
- ✓ The powered microdebrider is the 'gold standard' for papilloma removal in the larynx.
- ✓ Spread to the tracheobronchial tree is associated with a greatly worsened prognosis.

FUTURE RESEARCH

- ➤ JORRP has a great impact on the child's life during active disease and constitutes a big surgical load for the surgeon. While the majority of patients enjoy spontaneous remission, a small number continue to develop distal disease which may be fatal. Improvement in surgical technologies have reduced operative time and improved operative morbidity.
- ➤ There is consistent level 3 evidence that cidofovir extends the treatment interval and promotes remission of disease. Consolidation of this evidence will require multicentre collaboration in order to standardize protocols and increase patient recruitment. Such a multicentre initiative has already been proposed to seek critical genes in the pathogenesis of RRP.[73]
- ➤ The future of the management of RRP lies in a better understanding of its pathogenesis.
- ➤ Trials for the HPV vaccine have yet to demonstrate any therapeutic efficacy for children with established RRP while immunological and clinical benefit has been shown in pilot studies in adults. Longitudinal studies will also be needed to explore the impact of HPV vaccination on the pathogenesis of RRP in a preventative role, as with cervical cancer.
- ➤ Despite extensive and sophisticated molecular immunology research, the precise relationship between the human papilloma virus, host immunity and the development of papillomas eludes us. The elucidation of this relationship holds the key to conquering this disease.

KEY POINTS

- Juvenile respiratory papillomatosis can affect any part of the respiratory tract.
- While it is uncommon, its management can constitute a major surgical burden to the otolaryngologist.
- The mainstay of treatment is by surgical debulking.
- The role of adjuvant therapy is uncertain but supported by level 3 evidence.
- In the majority of cases, the disease goes into spontaneous remission.
- Some children develop uncontrolled disease, which in rare cases may be fatal.

CHAPTER 33

PAEDIATRIC VOICE DISORDERS

Ben Hartley and David M. Wynne

SEARCH STRATEGY

Data in this chapter may be updated by a Medline search using the keywords: paediatric, voice and dysphonia.

INTRODUCTION

There have been tremendous advances in the understanding of voice disorders and their management in recent years. The subspecialty of phoniatrics has evolved principally in adults and this knowledge may now be applied to voice disorders in children. Disorders of voice – where the predominant symptom is hoarseness or 'dysphonia' – must be distinguished from disorders of speech, articulation and language. Speech and articulatory disorders are characterized by difficulty in producing speech sounds, often in the presence of normal laryngeal function. In language disorders, the child uses words and sentences inappropriately, again usually despite normal laryngeal function.

Voice disorders are largely a manifestation of laryngeal pathology. Six to 23 percent of 5–18 year olds have some form of voice 'problem'.[1, 2] In school aged children 6–9% of children have been reported to have a voice disorder.[3] Actual prevalence rates are thought to be higher as many children present directly to speech and language therapy rather than direct to paediatric otolaryngology.[4] In the UK it is estimated that the prevalence is around 6% when perceptual evaluation was undertaken by speech and language therapy and around 11% based on parental reporting.[5, 6]

The identification and subsequent management of paediatric voice disorders is important. Paediatric dysphonia may negatively impact on a child's education, emotional and psychosocial development.[7, 8]

In adults the European Laryngological Societies (ELS) recommend evaluation of five parameters of voice, namely perceptual evaluation, videostroboscopic evaluation, aerodynamic performance, acoustic analysis, impact.[9] In children there is still much debate on the 'minimum' level of evaluation, especially if laryngoscopy requires general anaesthesia.[5, 6]

The spectrum of voice disorders seen in a specialist paediatric voice clinic is very wide. Patients range from child performers who have a normal conversational voice but whose parents have been concerned about a loss of the upper range of their singing voice, to children with severe congenital or acquired laryngeal disease with no voice at all.[6]

With careful assessment, voice therapy and occasionally surgical intervention, most paediatric dysphonias can be corrected or improved.

GROWTH AND DEVELOPMENT OF THE LARYNX

The paediatric larynx is quite different from that of the adult (**Figure 33.1** and **Table 33.1**). The embryonic development of the larynx is described in detail in Vol 3, Chapter 58, Anatomy of the larynx and tracheobronchial tree. This section focuses on those aspects relevant to voice disorders and on normal growth and development after birth. Current knowledge stems largely from the detailed studies of Hirano et al.[10, 11]

Figure 33.1 Normal larynx in a 6-month-old child.

TABLE 33.1 Differences between the larynx of an adult and child

Feature	Difference
Size	The paediatric larynx is relatively smaller
Position	The child's larynx is relatively higher
Shape	Curled epiglottis, shorter vocal folds
Mucosa	More reactive and prone to airway obstruction Croup is uncommon in adults
Laminar vocal fold structure	Immature in young children

Elongation of the vocal folds

Hirano found that up to the age of 10 years, the length of the vocal fold was very similar in both males and females (6–8 mm). At puberty there is a substantial increase in growth, much more marked in males with the membranous vocal fold increasing to 14.8–18 mm (more than double). In females the increase is to 8.5–12 mm – an increase in length of a third. The cartilaginous portion of the vocal fold also grows with age but less rapidly, with a relative increase in the ratio of the membranous to cartilaginous vocal fold from 1.5 in the newborn to 4.0 in the adult female and 5.5 in the adult male. Hirano devised the concept of the respiratory glottis posteriorly with a wider aperture and the phonatory glottis anteriorly. These concepts are useful in planning surgical procedures. For example, in bilateral vocal cord paralysis it is possible to increase the airway by performing an ablative procedure, such as a laser arytenoidectomy. If this procedure is kept to the posterior part of the larynx, the anterior membranous vocal fold can be preserved for phonation.

Changes in vocal fold laminar structure

Much has been written about the layered structure of the vocal folds and its importance both to the understanding of disease and the development of phonosurgical treatment.

The five layers of the vocal fold are the **epithelium, superficial layer** of lamina propria (Reinke's space), the **intermediate layer** and **deep layer** of the lamina propria and the **muscle layer**. The first two are referred to the as the 'cover' and move freely over the deeper layers which form the 'ligament' and 'body' of the vocal fold.

This laminar structure is not present at birth, but starts to differentiate over the first few months of life. It becomes more developed throughout childhood and the adult form is quite easily recognizable by puberty. One surgical implication of this is that microflaps are more difficult to raise in early childhood due to a less well-developed plane for dissection in the superficial lamina propria.

Changes in pitch

An important feature of the paediatric voice is its pitch. This drops throughout infancy and childhood in males and females, with a marked change at puberty, particularly in males. This change in pitch corresponds to the anterior growth of the thyroid cartilage in response to testosterone and coincides with the development externally of the thyroid prominence or Adam's apple. The fall in pitch is approximately proportional to the growth of the membranous vocal fold.

ASSESSMENT OF THE CHILD'S VOICE

Children with voice disorders may present to a general clinic or to a specialist voice clinic. An otolaryngologist and speech and language therapist should staff paediatric voice clinics. Videostroboscopic equipment and the expertise to use it should be available. The history and basic otolaryngological examination is the same in both settings. Whether laryngeal videostroboscopy and/or speech therapy assessment is required will depend on the clinical situation.

History and examination

Mild or moderate dysphonias that have been present for some time tend to be accepted as part of the child's personality and not a medical disorder. Often, an incidental remark years later leads to the parents seeking medical assessment to exclude an underlying disorder. Some children and families see no problem with their dysphonia. Alternatively, some children and families find a mild

dysphonia very troublesome, particularly if they are performers or have aspirations to perform.

Information should be sought from both the child and the parents. If the problem has been present from birth, a congenital lesion is likely. However, a history of endotracheal intubation around the time of birth or around the time of onset of symptoms may suggest laryngeal stenosis, cricoarytenoid joint fibrosis, intubation granuloma or cyst formation. Much more commonly, symptoms start with an upper respiratory tract infection that has been accompanied by laryngitis, a situation made worse by habitual patterns of voice misuse.

The severity of the disorder may range from a loss of singing voice to complete loss of conversational voice. The time course of the dysphonia is also important. For example, dysphonia is often persistent with discrete vocal fold lesions and rarely returns to normal, although it may fluctuate and fatigue during the day.

Enquire about symptoms suggestive of gastro-oesophageal reflux, as this may irritate the larynx and cause dysphonia. Post-nasal drip associated with allergic rhinitis will do the same, particularly if there is a habit of forceful or constant throat clearing. Cough is quite harsh on the vocal mechanism and constant coughing associated with respiratory disease may lead to hoarseness.

Restrictive respiratory disease may cause reduced infraglottic pressure and subsequent dysphonia. The use of corticosteroid inhalers can also cause dysphonia and this can be helped by modification of drug regime or possibly inhaler technique and the use of spacer devices.[12]

Hearing loss may make the child shout. This can be the underlying cause of a dysphonia secondary to vocal misuse. Voice misuse – shouting – is common in children and may lead to disorders of hyperfunction such as nodules. Other abusive behaviours, such as smoking and alcohol, may occasionally be relevant.

It is extremely important to enquire about exercise intolerance and stridor, symptoms and signs that may be caused by laryngeal stenosis. Swallowing problems or choking may be the first indication of laryngeal paralysis. A general otolaryngological examination, including assessment of the ears and hearing, should be performed. Important clues can be gained by carefully listening to the quality of the child's voice during history taking. Laryngoscopy should be undertaken in all cases.

Laryngoscopy

The objectives of laryngoscopy are twofold, first to identify any structural lesion, such as a vocal nodule or papilloma, and second to assess laryngeal mobility during phonation.

Older children may be cooperative enough for indirect laryngoscopy but examination of the paediatric larynx has traditionally been performed under general anaesthetic. Detailed structural information can be obtained but little information is gained with regard to mobility. It is usual to watch vocal mobility on awakening from general anaesthesia. This can provide information with regard to vocal paralysis, but it should be recognized that by today's standards this is a very crude method of assessment. Awake laryngeal and voice examination should be the standard of care in a compliant child.

Most focal lesions can be excluded by awake fibre-optic laryngoscopy. This can be performed on a child of almost any age. It is usually quite straightforward, performed transnasally with a 2.2 mm fibre-optic endoscope. The optics of the larger fibre-optic endoscopes are better and, if possible, a 4 mm endoscope should be used. These larger fibre-optic endscopes are commonly being replaced with newer 'chip in the tip' videoendoscopic systems. These give an excellent view of the larynx with high quality images.[5, 6] From age 1 to age 5 years, compliance is limited and general anaesthesia and microlaryngoscopy may need to be considered. Some images are of sufficient quality to permit stroboscopy with examination of the mucosal wave.

Rigid laryngoscopy requires significant cooperation, which can only be obtained in children over 6 years of age. High-quality images of the larynx combined with stroboscopy give unparalleled information on vocal fold movement and structure. They also provide an important educational tool for parents and older children. Paralysis of a vocal cord is generally obvious but this technique gives insight to more subtle mobility disorders such as limited posterior glottic closure (glottic chink) and supraglottic constriction. This degree of information is useful and relevant to planning voice therapy.

ACOUSTIC ANALYSIS

With greater availability and use of computerized speech systems, acoustic data are increasingly being recorded. Unfortunately, in the paediatric population (unlike adults) there are no agreed protocols or standards to compare studies from different centres.[9] The most useful acoustic comparison in keeping with ELS guidelines would be measurements of perturbation.[13, 14] There is ongoing research and much debate in how to advance this.

PERCEPTUAL EVALUATION

Perceptual evaluation is one of the most important and available measures of voice. The most common scales currently used are 'GRBAS' and 'CAPE-V'.[15, 16] Both of these were developed for adult voice disorders and completion of the full data set may be difficult in children.

IMPACT/QUALITY OF LIFE

Although there are numerous questionnaires designed to assess the impact of a voice disorder, these were developed for adults. There have been a few developed for children based on their adult counterparts, including paediatric VOS,[17] paediatric V-RQOL,[18] paediatric VHI.[19] One of the issues with paediatric questionnaires is that the parent/carer is acting as a proxy for the child and their view may not match.[20] There is increasing evidence that children should be self-assessed and questionnaires are being designed for this purpose.[21]

SPECIFIC DISORDERS

Vocal nodules and functional voice disorders

Vocal nodules – now regarded as an organic manifestation of laryngeal hyperfunction – are the commonest cause of dysphonia in children (**Figure 33.2**).[22] The mainstay of treatment is voice therapy to correct the hyperfunction. While in adolescents this therapy is similar to that employed in adults, different strategies are necessary in younger children.

The traditional view, based on clinical experience, was that most vocal nodules in children could be expected to improve at puberty.[23] Puberty is a time of great change in the larynx, with tremendous growth of the membranous vocal fold in the male and, to a lesser extent, in the female. One can see how the dynamics of vocalization might change with potential improvement in the nodules. Mori,[24] however, reported that 12% of nodules did not improve at puberty. In the same study it was found that those treated with vocal hygiene alone (i.e. general advice regarding voice care) did not improve. Those given voice therapy under the supervision of a speech and language therapist did tend to improve and the degree of improvement was related to the number of therapy sessions. The essentials of voice therapy include reduction of vocal strain. Various techniques can be employed to reduce shouting, whispering, coughing and throat clearing and to encourage the use of a smooth easy voice. Periods of quiet play are recommended after noisy activity (e.g. football) to allow vocal fold recovery.

Surgery for nodules is rarely recommended in children. Concerns about the potential effects of scarring are very real. On occasion it can be justified when prolonged voice therapy has failed. Bouchayer and Cornut[25] reported cysts, polyps and sulci in children previously diagnosed as having nodules when examined at microlaryngoscopy. Some children with nodules have vocal cord cysts with a nodule on the contralateral cord and this might explain why some fail to respond to voice therapy. The use of videostroboscopic techniques in the voice clinic should help diagnose these conditions earlier. Cysts are treated by microsurgical excision.

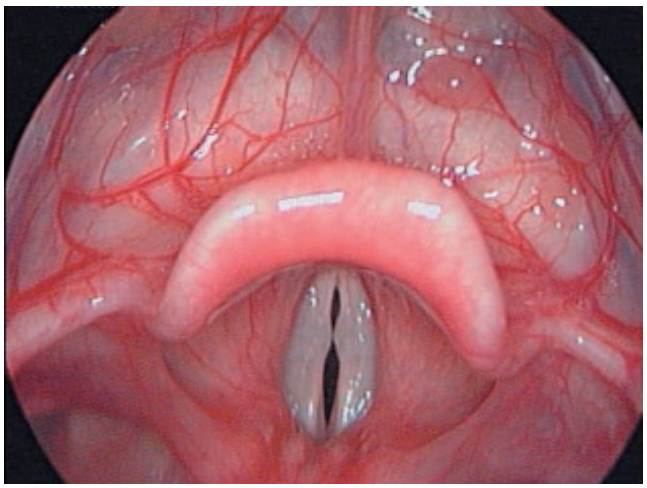

Figure 33.2 Vocal cord nodules.

A wide range of functional voice disorders can be demonstrated in children without demonstrable nodules. These children may present with dysphonia, or even aphonia, secondary to underlying psychological factors. For these children, voice therapy may need to be combined with a psychological assessment. Aphonia in the presence of a normal laryngoscopy evaluation is suggestive of psychological disturbance. A normal cough or laugh adds support to this contention. Puberphonia, when the prepubertal voice persists into adolescence or adulthood, is another condition associated with psychological disturbance. Highly specialized voice therapy, possibly in conjunction with a psychologist, is important to help these children develop an adult voice.

Laryngeal papillomatosis

A detailed account of laryngeal papillomatosis is given elsewhere (Chapter 32, Juvenile-onset recurrent respiratory papillomatosis). From the voice perspective, there are a number of important considerations.

The emphasis of modern surgical techniques is to minimize damage to the underlying lamina propria and to restrict surgery to the papillomas. In this way, voice quality will be optimized in the long term. Glottic scarring and webbing are well-known complications of surgical intervention with the laser.[26] The use of a microdebrider and cold steel instruments has much to commend it. After all, surgery cannot cure papillomatosis. Medical treatments have been advocated including intralesional acyclovir with some reported success.[27] In theory, any medical adjunct that reduces the number of surgical procedures would be beneficial in terms of voice preservation, although voice outcomes following these therapies have yet to be reported. Cidofovir is showing some promise and its use is considered in Chapter 32, Juvenile-onset recurrent respiratory papillomatosis.

Intubation injuries and voice

Much has been written about acquired subglottic stenosis consequent on prolonged endotracheal intubation in premature infants. Surgical techniques have evolved to correct this abnormality and allow eventual decannulation.[28–31] Voice problems following this surgery have been documented and are not uncommon.[32]

Subglottic stenosis is just one example of laryngeal injury caused by intubation. More minor scarring may affect the voice but not the airway (**Figures 33.3** and **33.4**). Damage to the vocal fold or underlying lamina propria causes dysphonia. Cricoarytenoid joint fixation and posterior glottic scarring may also be caused by endotracheal intubation and reduce vocal fold mobility. It is easy to confuse these conditions with vocal cord paralysis.

Voice therapy can be successful in some children. Surgical treatment of voice problems caused by intubation trauma remains a significant challenge. There is

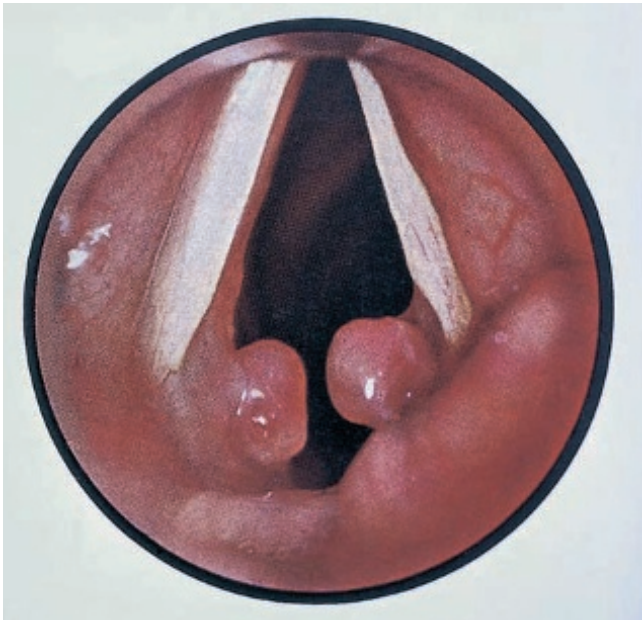

Figure 33.3 Intubation granulomas.

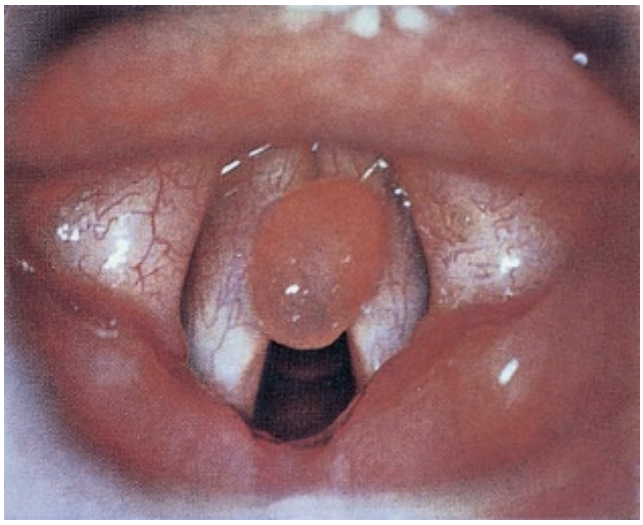

Figure 33.4 Vocal cord polyp following prolonged endotracheal intubation.

potential for the introduction of medialization techniques in this group of children, but there must be an adequate airway before this can be considered and this situation is uncommon.

Vocal cord paralysis

In general terms, children with bilateral vocal cord paralysis have a good voice or cry. It is the airway that gives concern. Spontaneous recovery of function takes place in some, but after 2–3 years of observation this is unlikely to happen.[33] A number of lateralization procedures can be performed to develop a wide posterior glottis for respiration while preserving the anterior glottis for phonation. Either laser arytenoidectomy[31, 34, 35] or endoscopic suture lateralization can achieve these goals.

In contrast to bilateral cord paresis, children with unilateral cord paralysis present with aspiration and a weak cry. The airway is relatively spared. Most improve with time due to compensation from the contralateral nonparalyzed vocal fold or to spontaneous recovery.

Medialization thyroplasty can be considered for those who do not improve and continue to have a significant voice problem. However, there is limited published information on this and it should be remembered that its efficacy to diminish aspiration has been limited.[36]

The concept of placing a silastic implant before puberty has raised concerns that this might interfere with the anticipated physiological growth spurt. It is the author's practice to consider medialization using a fat injection in dysphonic, prepubertal children and to restrict silastic thyroplasty techniques for dysphonic post-pubertal patients. There is also increasing use of newer laryngeal injectables such as calcium hydroxyapatite in children.

The concept of re-innervation is attractive. In a series of eight children with unilateral vocal cord paralysis, three underwent implantation with ansa cervicalis/strap muscle pedicles. This, together with post-operative voice therapy, gave 'good' results.[37] There has to be some scepticism about these procedures as re-innervation techniques are capable of restoring laryngeal tone but have had limited success in achieving voluntary movement. Nevertheless, children seem to be the ideal population on which to carry out these procedures as nerve grafting in general is more successful in this age group.

It is worth restating that it should never be assumed that an immobile vocal cord is paralyzed. Vocal cord immobility in previously intubated children may be due to joint fixation or posterior glottic scarring. The distinction between these diagnoses is extremely important, particularly when vocal cord immobility is bilateral. The management of paralysis is conservative with a tendency towards spontaneous recovery. Fixation and scarring do not improve and children may be subject to years of unnecessary waiting with a tracheotomy before a surgical lateralization procedure is contemplated.

Tracheotomy and voice

Children with tracheotomies will often have impaired voice; this may also result in a speech and communication delay. This is only partly due to the tracheotomy tube diverting air from the glottis. The main factor is usually the laryngeal lesion that required tracheotomy formation in the first place. Children with a healthy larynx can obtain good voice by occluding the tube on expiration (with a finger or speech valve) and projecting air around the tube and up through the glottis. To facilitate this, the tube needs to have sufficient space around it and may need to be 'downsized'. This is usually possible without restricting the airway. Speech valves are frequently used in the author's practice for children. As well as helping with speech they help with secretion management and swallowing.

BEST CLINICAL PRACTICE

- ✓ Laryngeal microflaps are more difficult to raise in early childhood due to a less well-developed plane for dissection in the superficial lamina propria. **[Grade A]**
- ✓ An immobile vocal cord is not always paralyzed. Consider joint fixation and posterior glottic scarring, especially if the child has been intubated.
- ✓ The term 'vocal abuse', often used to describe adult dysphonias, is best replaced by 'voice misuse' in the paediatric setting. Beware the sensitivity of recording the word 'abuse' in children's records.
- ✓ Advances in endoscopic equipment are such that awake laryngeal and voice examination should now be the standard of care in a compliant child.
- ✓ Due to the potential for permanent scarring, surgery for nodules is rarely recommended in children. It should be considered only as a last resort when prolonged and skilled voice therapy has failed.

FUTURE RESEARCH

- ➤ **Laryngeal transplantation for voice.** Perhaps the most challenging of paediatric voice conditions is the child with no voice due to complete laryngeal stenosis which is beyond surgical reconstruction. Such children are encountered after severe burns or caustic ingestion. They are tracheotomy-dependent and communicate with signing and non-oral devices. Laryngeal replacement using transplantation carries the best hope for these children and, although there has been one successful adult patient, this has yet to be repeated.
- ➤ **Re-innervation of the paralyzed larynx.** Phonosurgery can be helpful for the voice in laryngeal paralysis with medialization using injection or thyroplasty techniques. However, the biggest concern for children with laryngeal paralysis is not voice but aspiration. We do not have a universally accepted solution for aspiration due to laryngeal incompetence. Withdrawal of oral feeding and gastrostomy remains the mainstay. Fortunately, compensation frequently takes place for unilateral lesions but often not bilateral problems. Laryngeal re-innervation may hold the key but it is still in its infancy.
- ➤ **Repair of damaged vocal cords with synthetic 'SLP'.** Vocal cords damaged by intubation or surgery have lost the mucosal wave due to destruction of the important superficial layer of the lamina propria (SLP layer). Medialization of damaged vocal cords has had only limited success and attempts are being made to create a synthetic substitute for this important gel layer for potential replacement by injection into Reinke's space.

KEY POINTS

- Voice disorders in children are common; few require medical intervention.
- The impact of dysphonia in children should not be dismissed.
- A diagnosis can usually be made by careful history taking and examination to include laryngoscopy and ideally videostroboscopy.
- The child's perceptual reporting should be sought.
- Laryngeal muscle hyperfunction with or without nodules constitutes the commonest group of disorders.
- These disorders respond well to skilled voice therapy (speech and language therapy - 'SALT').

CHAPTER 34

FOREIGN BODIES IN THE EAR, NOSE AND THROAT

Adam J. Donne and Katharine Davies

SEARCH STRATEGY

Data in this chapter may be updated by PubMed searches using the keywords: foreign body and ear, nose, throat, inhalation and oesophagus. The searches returned the following numbers of articles: ear, nose, pharynx, larynx and trachea/bronchus. The majority of the articles identified were level 3 in the form of retrospective reviews.

Hospital episode statistics data were accessed via the public access website. The Susy Safe project statistics were accessed via a public access website.

INTRODUCTION

For the purposes of this chapter a 'foreign body' is an object or substance that is inappropriately situated in a particular anatomical location. Children commonly present with a foreign body in the ear, nose or throat. Young children tend to explore using their mouths and this puts them at risk of the foreign body entering the aero-digestive tract.[1] Impaired behavioural development due to a neurological diagnosis or attention deficit/hyperactivity disorder[2, 3] may increase the risk of foreign body insertion, ingestion/inhalation. In adults, poor dentition, alcohol consumption and old age may be important factors for eating-related airway obstruction.[4] Adults may also have neurological or psychological factors.[5]

Child abuse by neglect or direct non-accidental injury (NAI) may be relevant. However, adults also present with foreign bodies which may be due to a chance event or accident (e.g. pin inhalation or an insect in the ear) or may herald an underlying pathology (e.g. oesophageal malignancy and food bolus obstruction). Foreign bodies can be categorized by location and type. The location of the foreign body may be life-threatening as in the larynx, or benign, such as a bead in the ear. They can be subdivided into organic and inorganic. The nature of the foreign body may pose a direct threat to tissue (e.g. battery ingestion).

INCIDENCE

The largest active registry of non-food foreign body incidents is the Susy Safe project.[6] The number of foreign body incidents in the European Union in children aged 0–14 years is 50 000 per annum, and 1% are fatal. Around 10 000 are inorganic and 2000 involve toys.[6] Unfortunately, it has been reported that up to 22% have a repeat of the foreign body incident,[7] therefore education must be essential for the long-term management of this risk.[8]

It is difficult to determine the relative frequency of foreign bodies within the trachea, bronchus and oesophagus compared to ear and nose as little has been published to demonstrate the complete range of ear, nose and throat foreign bodies in any particular series. A literature review would indicate foreign body frequency is higher in ear and nose compared to throat.[9] An eastern European retrospective study (over 10 years with 849 patients) identified the following relative proportions: tracheobronchial 11%, pharyngo-oesophageal 17%, and ear, nose and post-nasal space 72%.[10] Using data from the Susy Safe project, it is possible to determine the following relative percentages for foreign bodies: ear 25.9%, nose 27.4%, pharynx and larynx 4.3%, trachea, bronchus and lungs 12.8%, and mouth, oesophagus and stomach 29.7%.[11] This Susy Safe publication used ICD9-CM codes and reported on a total

of 8593 incidents. As the categories differ from the eastern European study, it is not possible to make close comparisons. However, it is clear that ear and nose form around half of the incidents recorded. Both studies agree that incidents affecting the tracheobronchial region constitute around 11–12%. The Susy Safe project identified that foreign bodies were food in 26% of cases. The data specifically for food-related foreign bodies indicates a difference in proportions of anatomical site affected: ear 7%, nose 19%, pharynx and larynx 16%, trachea, bronchus and lungs 50%, and mouth, oesophagus and stomach 8%.[12] Clearly, there is a different profile, which might be explained by the fact that the Susy Safe project originally attempted to identify non-food foreign bodies with only later collection of food foreign bodies. A further compounding factor is that different countries and cultures eat different food types, which may be significant and skew the data.

Self-inserted foreign bodies may occur more frequently in children with attention deficit or hyperactivity disorder.[2] Children with neurological disorders have been shown to present later with foreign body in the aerodigestive tracts. Furthermore, these children remain in hospital for longer and may have a more complicated management.[13] For children who are otherwise healthy before foreign body inhalation, reviews suggest that the majority (96%) did not require supplementary oxygen support beyond 2 hours.[14] This implies that, even though foreign body inhalation is potentially life-threatening, for most patients the removal is without complication. If there is a pre-operative respiratory impairment, the risk of post-operative complication is higher.[15] Immediate post-operative chest radiographic features are predictive of pulmonary complications.[16] However, the mortality for foreign body inhalation is still high.

Hospital Episode Statistics (HES) data for Accident and Emergency admissions in England are available online from the Health and Social Care Information Centre (hscic) at NHS Digital.[17] These data indicate that for the years 2011–2012 and 2012–2013 the attendances for 'foreign bodies' as a group represented about 1% of attendances – and during 2012–2013 there were a total of over 18 million Accident and Emergency attendances. These data are crude as there is no indication of the anatomical location of the foreign body. However, it is clear that foreign bodies are an important problem.

The Susy Safe project was supported by the European Commission and resulted in the development of toy safety directives which aim to make small parts on toys safe for children 0–3 years but also control the use of heavy metals in toys. In general, boys tend to present with foreign body incidents more commonly than girls[18] and they are more frequently involved with more severe injuries.[19] However, when the foreign body is jewellery, 76% of those presenting are female.[20]

EAR FOREIGN BODIES

Right-handed children tend to insert foreign bodies into their right ear and left-handed children into their left ear.[21] However, bilateral foreign bodies have also been reported in ear (and nose).[22]

Inert foreign bodies may be identified as an incidental feature.[18] However, as there are significant consequences of delayed removal of certain items (e.g. button batteries) examination is appropriate with a positive history. The isthmus of the external auditory meatus is the narrowest section and foreign body impaction may occur at this point. Many aural foreign bodies will migrate out of the ear. Grommet extrusion is testimony to this fact. The urgency of removal of foreign bodies should be based upon the foreign body in question. Potentially corrosive foreign bodies should be removed without delay. However, inert foreign bodies are often found incidentally in the ear and nose as they are asymptomatic in 47% and 43% of cases respectively.[18]

Management of ear foreign bodies

A variety of techniques to remove aural foreign bodies exist and the technique adopted is determined by the foreign body characteristics (i.e. size, shape, consistency), position and cooperation of the patient. A smooth, hard foreign body (e.g. bead) is difficult to grasp and evidence suggests that non-graspable foreign bodies are better removed by otolaryngologists with fewer complications compared to emergency department staff removal.[23] Methods include microsuction, wax hook and irrigation.[24] The cooperation of the child is essential and up to 30% require a general anaesthetic to allow safe removal.[25] It has been reported that up to 47% sustain trauma such as laceration and tympanic membrane perforation. Approximately half have had previous attempts before seeing an otolaryngologist,[26] which suggests that aural foreign bodies should be dealt with by otolaryngologists as a matter of course.

Irrigation should be a safe technique as long as the tympanic membrane is intact. Studies indicate that the pressure exerted may be sufficient to cause tympanic membrane rupture, ossicular disruption and round window fistulae.[27] If the irrigation fails to expel a foreign body which is organic (e.g. dried pea), swelling may occur, which can result in further removal difficulty and pain due to pressure exerted against the canal wall skin.[25, 28] Adults more frequently present with insects in their ears (**Figure 34.1**). These cause irritation and distress and a consequent urgency to remove.[26]

NASAL FOREIGN BODIES

A nasal foreign body must be considered in any child with unilateral nasal discharge (especially with unilateral excoriation of nasal rim).[29, 30] The most common age of presentation is 2–4 years. A nasal foreign body usually requires a minimum of 4 days before discharge occurs[22] unless it is a button battery when discharge is immediate. Inert nasal foreign bodies may be present for a considerable number of years.[31, 32] With prolonged indwelling a foreign body granulation develops (**Figure 34.2**) and may result in rhinolith formation. Rhinoliths consist of salts of

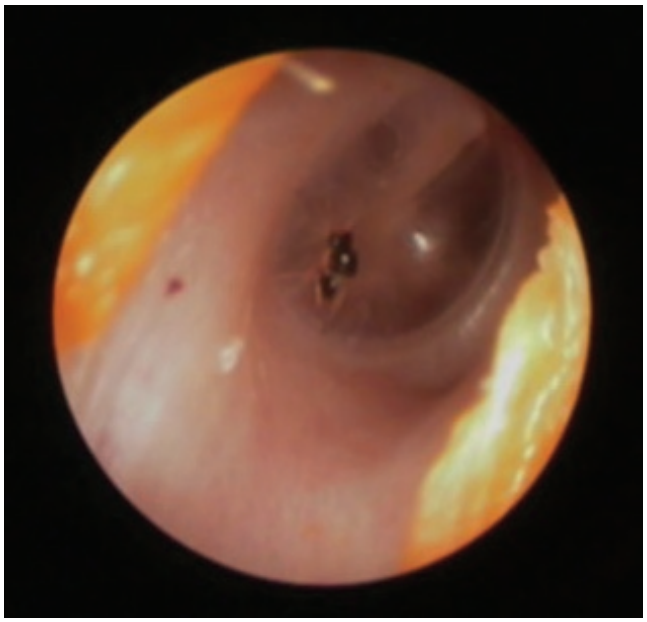

Figure 34.1 Otoscopic image of an insect in an ear.

calcium, magnesium phosphate and carbonate[33] and are radio-opaque.[34] A long-standing nasal foreign body may even result in hypoplasia of the inferior turbinate.[35]

Management of nasal foreign bodies

The usual technique for removal of a nasal foreign body is the placement of a hook or preferably a bent Jobson Horne probe over and behind a foreign body. The foreign body is then pulled forward.[36] If the foreign body moves posteriorly, there is a theoretical risk of inhalation.[37] Other techniques include the 'mother's kiss' whereby there is mouth-to-mouth gentle blowing into the mouth of the child with the unaffected nostril being held closed. This may allow the foreign body to be expelled in around 60% of cases.[38] Hollow foreign bodies may be resistant to this technique.[39] Balloon catheters (Fogarty) have also been used placed intranasally behind the foreign body then partially inflated and pulled out of the nose, bringing the foreign body ahead of it.[40] Occasionally, it may be difficult to remove a foreign body through the anterior nose and therefore pushing it into the pharynx of the anaesthetized patient is an option for removal.[41] An alternative may be to break the foreign body *in situ* and remove it in numerous pieces.[35]

There is a risk that nasal foreign bodies may be inhaled;[42] however, this is more probable if the gag reflex is impaired. A foreign body falling into the laryngopharynx would usually be swallowed or coughed up. In the past, many of us were taught that 'the sun should never rise or set on an inhaled or ingested foreign body' but it is almost certainly safe to leave nasal foreign bodies in neurologically normal children for operative removal during normal working hours if required.

INHALED FOREIGN BODIES

Most inhaled foreign bodies occur in the under 3 years age group.[11, 43, 44] They are more common in boys than girls.[45] In children younger than 3 years the foreign body is typically organic (food) whereas in children older than 5 years they are more often inorganic.[46] A large variety of foreign bodies have been published.[47, 48] The lack of molar teeth is thought to be significant due to the reduced ability to chew food adequately.[1, 49] Young children tend to put objects in their mouths which may additionally explain the high incidence of foreign body aspiration.[50] The mortality from foreign body inhalation is around 1% and the commonest cause of accidental death in children under 3 years of age. Foreign bodies in the tracheobronchial system seem to cause more complications that in other anatomical sites.[51]

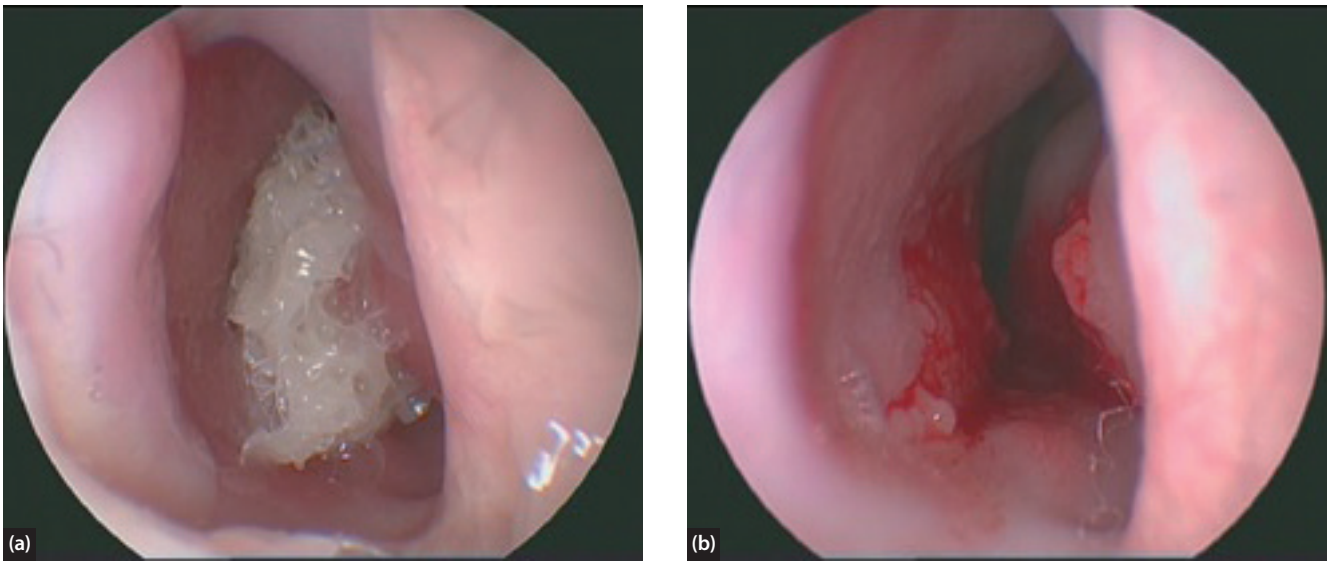

Figure 34.2 Endoscopic images of a fabric foreign body in a nose **(a)** and the immediate post-removal appearance of granulation at the point of contact with the foreign body **(b)**. This indicates chronic contact.

It has been shown that children are often able to clear their own airways, but this ability is less well developed in the younger the child. In one report 85% of inhaled objects were cleared before emergency medical services arrived at the scene. Food and coins have been identified as the main culprits.[52] In 1975 Heimlich published a report on a manoeuvre to expel laryngeal foreign bodies.[53] A report suggests that this manoeuvre may be responsible for reducing deaths in the under 15 years age group from foreign body inhalation.[54] There may be significant complications to the procedure but doing nothing commands a greater risk. Serious complications include oesophageal-gastric rupture,[55, 56] diaphragmatic hernia[57] and emphysema (in subcutaneous space[58] and mediastinum[59]).

Inhaled foreign body presentation may vary depending upon the exact site of obstruction with the airway. The history may present with a witnessed foreign body in the mouth or even no apparent foreign body presentation in a young child, and this can delay diagnosis. Symptoms and signs of foreign body inhalation include choking, coughing, hoarseness, shortness of breath, wheeze, increased work of breathing, cyanosis, asphyxiation and death. Foreign bodies arising anywhere within the large respiratory airway may result in stridor. Laryngeal foreign bodies may give rise to hoarseness which is unlikely with an object in the right main bronchus. The history is paramount as a parent/guardian is present in about half (49%) the incidents and the child was eating in 34% of cases.[1] Indeed, even if the child is symptom free, if no object is fully expelled by coughing after a choking episode, further evaluation is indicated. A low threshold is essential so that the asymptomatic foreign body[60] or occult foreign body is not missed.[61] Delayed presentation is not uncommon in children and may have been treated as asthma due to the low-grade cough and noisy breathing. In almost 40% of cases the diagnosis was delayed for more than 24 hours.[48] One report of flexible bronchoscopy for respiratory symptoms (where foreign bodies were coincidentally identified) indicated that symptoms (due to the foreign body) were present from 1–132 months. The longer the duration of foreign body placement, the increased probability of long-term complications. When present for less than 1 month, all patients recovered completely but, if present for more than 3 months, only 30% recovered. The remainder had chronic cough and wheeze or bronchiectasis.[62]

The location of the foreign body within the airway has been identified from meta-analysis to be in decreasing frequency for the following locations: bronchus (right more frequent than left side),[63] trachea, larynx and lung.[48]

Laryngeal foreign bodies are relatively infrequent (2–12%)[64, 65] compared to the rest of the tracheal and bronchial incidence. They present with either partial or complete airway lockage. The former may result in voice issues (hoarseness), stridor, dyspnoea, prolonged atypical croup or even odynophagia[66] and as such can result in misdiagnosis and delay in identifying the laryngeal foreign body.[67] The latter will result in hypoxia and/or laryngospasm and death by asphyxiation[64] and classically require the Heimlich manoeuvre. The shape of the foreign body within the larynx is either spheroid or flat.[68] However, sharp metallic items that may penetrate the vocal cord or wall of trachea such as safety pins present a surgical challenge.[69, 70, 71] Within the larynx foreign bodies can be very difficult to identify even with spiral CT scanning.[72] If there is a delay in diagnosis, there can be significant associated granulation tissue at the glottis level where the foreign body is in contact with the mucosal surface, similar to the bronchus.[73]

Radiographic findings on chest films will often be normal (11%–26%)[74, 75] unless there is a radio-opaque foreign body present.[48] Additional radiographic features include atelectasis, hyperinflation, mediastinal shift, pneumonia and pneumothorax. Classically there is hyperinflation of the lung on the side of the foreign body due to the 'ball-valve' effect. The intrathoracic pressure is decreased on inspiration such that air can enter the bronchus. On expiration the intrathoracic pressure reduces to compress the bronchus (somewhat) around the foreign body (**Figure 34.3**). The sensitivity and specificity of radiographs for airway foreign bodies have been calculated to be 73% and 45% respectively,[76] which implies that the radiological investigation is an aid but should not deter an airway endoscopy. Fluoroscopy improves foreign body detection but even this additional modality radiology does not identify a significant proportion.[75]

Computed tomography virtual bronchoscopy is highly sensitive at identifying a foreign body within the airway[77] but, if this requires a general anaesthetic, most would consider a rigid bronchoscopy as the patient's condition may change suddenly while anaesthetized. In asymptomatic patients CT bronchoscopy may therefore be a reasonable option but it cannot replace endoscopy.[78, 79]

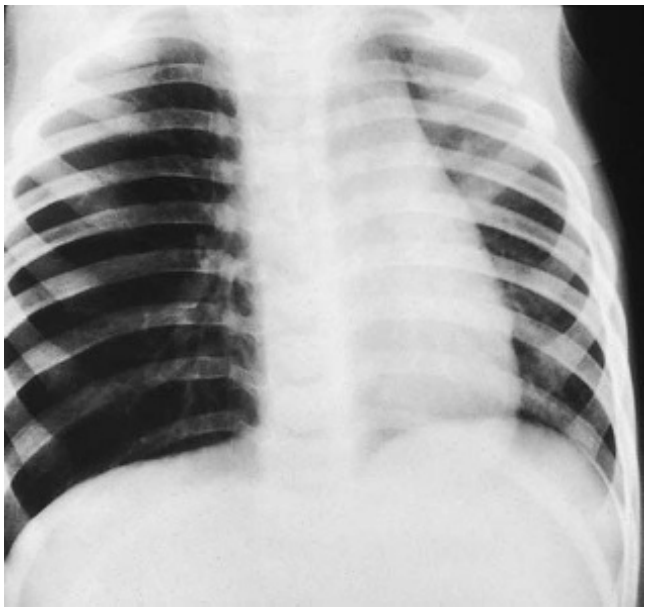

Figure 34.3 Chest X-ray showing hyperinflation of the right lung due to a foreign body in the right main stem bronchus.

Management of inhaled foreign bodies

Some surgeons advocate flexible bronchoscopy via a laryngeal mask or endotracheal tube to diagnose and remove foreign bodies.[80] Some have reported very high success rates,[63] and the benefit of flexible endoscopes is that they are flexible and able to approach the bronchus at a different angle. However, the flexible endoscope cannot ventilate the patient and presents a significant obstruction.[63] Flexible bronchoscopy may be possible in older children and adults without general anaesthesia but rigid bronchoscopy under the controlled conditions of a general anaesthetic is the mainstay for foreign body removal.[62] Use of the urological basket with flexible bronchoscopes has been reported in cases where rigid bronchoscopy has failed.[81, 63] There is genuine value in flexible endoscopy in the repertoire for foreign body removal.

A direct laryngotracheobronchoscopy or microlaryngotracheobronchoscopy (MLTB) should be performed to diagnose and remove the foreign body without undue delay. The level of urgency depends on the clinical condition of the patient and resources available. The endoscopy is best performed during daylight hours. If a child presents during an evening with a history of possible foreign body inhalation and is well, it is reasonable to delay endoscopy until the morning.[82] This remains somewhat controversial. The exceptions include unstable symptoms, type of foreign body (e.g. peanut, **Figure 34.4**), and broken seeds as these cause oil release and granulation formation,[83] beans (especially dried as these cause swelling and inflammation)[47] and batteries (see below).

MLTB for removal of foreign bodies is best performed for children using inhalation anaesthesia as this has been shown to be associated with fewer complications.[44]

MLTB to remove a foreign body is best performed in children without endotracheal intubation as there is a small risk that the foreign body may be lodged at the larynx or immediate subglottis and the endotracheal tube may push the object in such a way as to cause complete airway closure. It is therefore advisable that the rigid bronchoscope is ready for use. Furthermore, paralysis is not advised until the airway has been assessed and secured. Topical anaesthetic on the larynx prevents laryngospasm, which is undesirable during such cases.

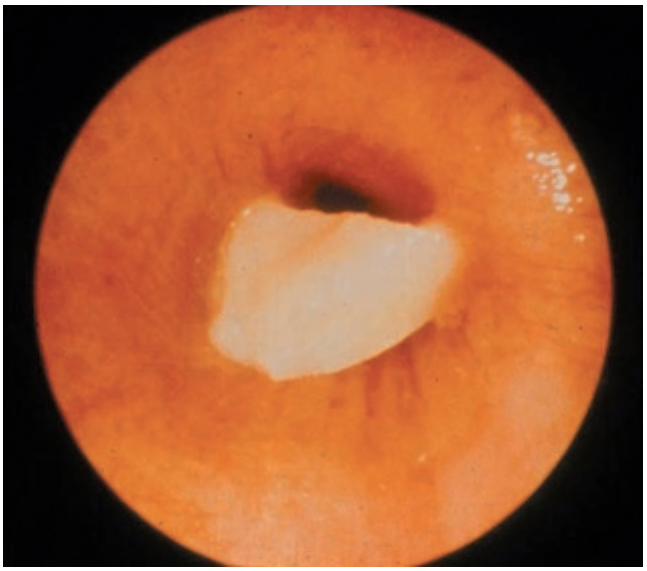

Figure 34.4 A peanut in the bronchus.

Topical adrenaline is very useful to decongest the area immediately around the foreign body, especially if there is any granulation present, with the inherent risk of bleeding.[63] On successful removal of the foreign body an immediate second look is necessary to ensure other fragments are not retained. Steroid is typically administered to reduce effects of oedema due to airway instrumentation as steroids have been well described to reduce oedema of airway surgical intervention and prolonged intubation.[84] Most patients require post-operative observation until the following day.

There is a reported risk of up to 4% for life-threatening complications following endoscopic removal of foreign bodies. The risks include pneumothorax (unilateral and bilateral),[47] tracheal laceration, pneumonia, haemorrhage into the airway, and cardiac arrest due to hypoxia.[85] Even if foreign body removal is successful, delayed pneumothorax can occur post-operatively. The risk of hypoxia during foreign body removal by MLTB is higher if the child is less than 1 year of age,[86] with certain types of foreign body[47] and the longer the duration of procedure.[44, 86] The latter may indicate the increased difficulty of removing the foreign body from the airway. Further risk factors for hypoxia for the patient during endoscopic removal include pre-existing pneumonia[87] and foreign body fruit seeds.[87, 88] Extracorporeal membrane oxygenation (ECMO) may be a useful technique to maintain oxygenation where the patient is too unstable and when the tracheal foreign body removal is otherwise impossible without complete airway obstruction and significant risk of cardiac arrest.[89] The risk of death during endoscopy for foreign body removal is significant and reported at 0.42%[90] yet a more recent study using USA nationwide data over 3 years indicated a death rate of nearer 1.8%.[91]

A negative MLTB is not a failure as the threshold to suspect foreign body inhalation must be low. The negative rate has been reported to be as much as 60%.[91] However, since delayed diagnosis occurs in a significant proportion and may result in bronchiectasis, the index of suspicion should be low.

In some circumstances it may be impossible to remove a foreign body using endoscopy. An alternative strategy may include tracheal fissure (as tracheostomy incision) for tracheal foreign bodies or thoracotomy for bronchial sites.[47]

INGESTED FOREIGN BODIES

A variety of foreign bodies are ingested by children. Peak incidence is in children less than 4 years of age (up to 75%). The most common item ingested is probably the coin (up to 70% of cases) (**Figure 34.5**). Symptoms include drooling, pain, dysphagia and odynophagia. Small, blunt foreign bodies may pass through unhindered. Foreign bodies such as chicken and fish bones may stick in the tonsil, tongue base, cricopharyngeus and pharyngeal wall

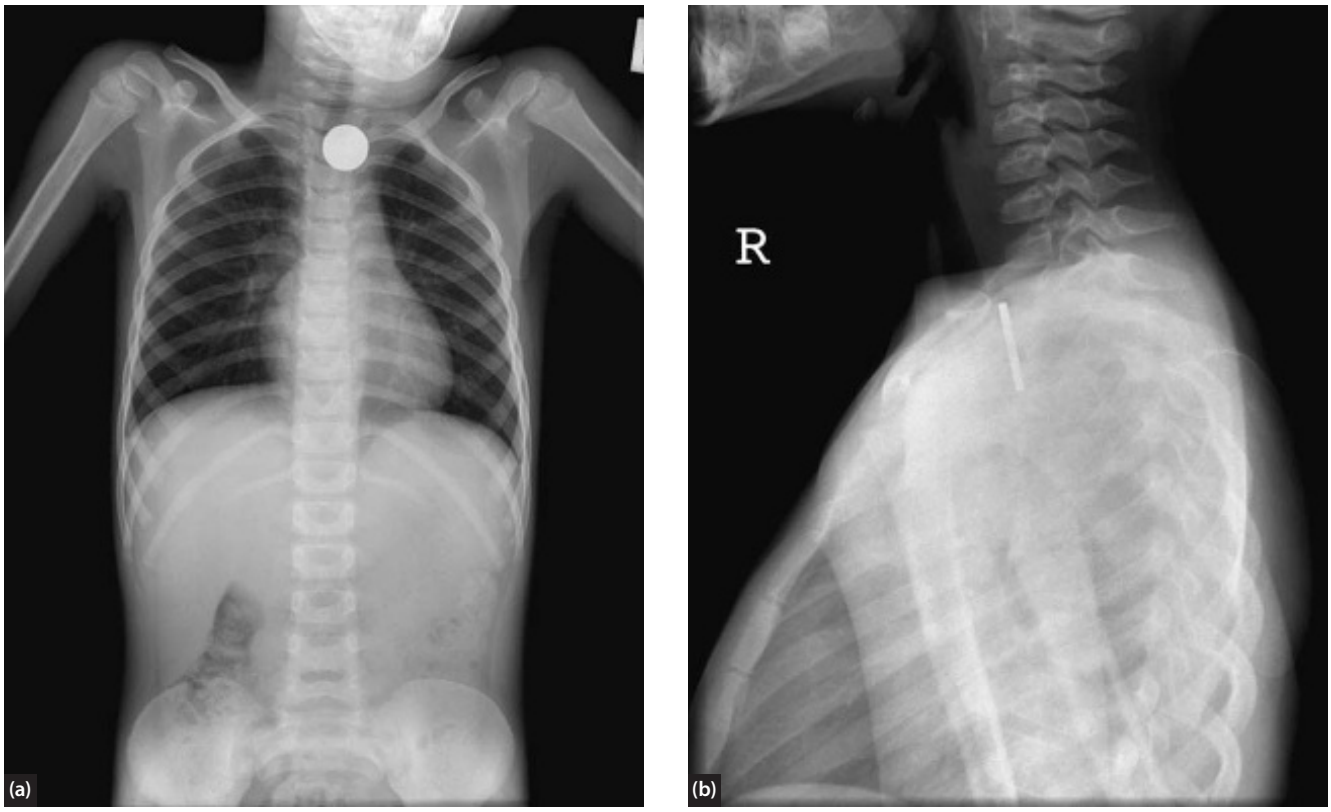

Figure 34.5 (a) Foreign body (coin) in the oesophagus. **(b)** The lateral view confirms the position.

in reducing order of occurrence.[92] Larger items typically stick at the cricopharyngeus or upper oesophagus above the aortic arch. Pathology within the oesophagus can present with foreign body impaction.[93]

Management of ingested foreign bodies

For food-related impaction, medical management is often trialled. Agents include hyoscine (buscopan) and diazepam. The evidence for the use of buscopan or diazepam in this situation is inconclusive. Small retrospective studies have indicated that effervescent fluids may confer some benefit.[94] Food bolus impaction is quite uncommon in children and should raise the possibility of eosinophilic oesophagitis. This condition is discussed in more detail in Chapter 44, Reflux and oesinophilic oesophagitis. When a food bolus is found in a child, the surgeon should take three biopsies from the lower oesophagus for histology and specifically request examination for eosinophils.

Flexible nasendscopy may either identify the foreign body in the pharynx or demonstrate saliva pooling in the pyriform fossae indicating a hold-up in the oesophagus. Metallic foreign bodies may be detected by metal detector or more usually radiography (see **Figure 34.5**). Contrast swallow is not an appropriate initial management as it obstructs endoscopy and may result in aspiration.[95]

Whereas foreign bodies such as small fish bones may absorb without removal, most will require surgical removal.[96] If not removed, some foreign bodies migrate into the soft tissue of the neck.[97] Controversy remains around the choice of flexible or rigid endoscopy (**Figure 34.6**). The latter has a significantly higher perforation rate compared to flexible type (0.2–1.2 versus 0.02–0.05),[98] yet both methods have similar success rates.[99] Early intervention confers benefit of reduced complications in particular for sharp foreign bodies such as bones and pins.[98, 100, 101] Complications include perforation, mediastinal infection/abscess, retropharyngeal abscess and oesophageal stenosis.[102] Delaying intervention beyond 24 hours may increase duration of therapeutic endoscopy.[103]

SPECIAL CONSIDERATIONS

Batteries and magnets

Special consideration needs to be given to batteries as foreign bodies. There has been a significant and increasing rise in battery foreign body incidents since one of the earliest reports of battery ingestion in the 1970s.[104] This was a camera mercury battery which was removed by gastrostomy. Between 1985 and 2009 there was a 6.7-fold increase.[105] The increase in incidence is thought to be due to the increased usage in small electronic devices, the size, shape and smoothness of the button battery and the extent of injury due to the battery power output.[106] There is a male preponderance (57%).[107]

Batteries cause harm in a variety of ways:

- soft tissue forming an electrical circuit between the terminals (sides) of the button battery, hydrolyzing tissue by forming hydroxide at the negative terminal[105, 108]

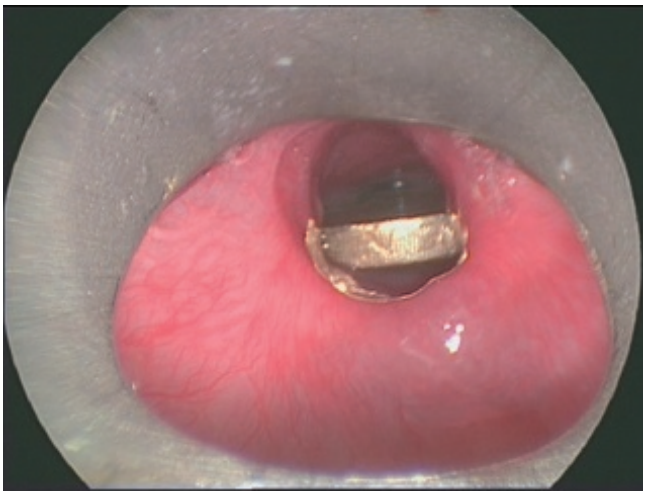

Figure 34.6 Image of a coin in the upper oesophagus on endoscopy.

- leakage of alkaline[109] from the battery when in a saline environment
- pressure necrosis[110] if compressed at a particular site
- release of toxic compounds[111] (e.g. mercury) to cause systemic toxicity.

The majority of batteries are the alkaline variety.[107]

The Susy Safe project has a button battery database component and a report on 348 cases has revealed the following anatomical sites affected. Most cases occurred in the mouth, oesophagus, stomach (188/348), nose (112/348) and ear (44/348).[106] There was only a single case of an inhaled battery. This report identified that 30% of children had dysphagia and perhaps surprisingly 26% had fever and cough.

The size of the battery seems to be important determinant for complications. The highest risk is a 20 mm battery in children under 4 years old.[105] A battery causes a rise in temperature and pH when ingested.[112] Burns occur within 2–2.5 hours. Fifty-four per cent of cases with a fatal outcome were misdiagnosed.[105] This indicates the importance of urgent X-ray investigation and removal. The X-ray feature of button batteries is a double contour.[107] The larger size of button battery is important as it may get stuck at sites of anatomical narrowing such as within the oesophagus at the arch of the aorta. If the battery is past the stomach, serial abdominal X-ray investigation may be appropriate. MLTB is also of value during pharyngo-oesophagoscopy and battery removal to rule out tracheo-oesophageal fistula or prodromal granulation within the airway.[113, 114, 115] Other complications of button batteries in the oesophagus include oesophageal perforation, haemorrhage,[116] vocal cord palsy,[117] ulceration/necrosis and death.[118] A report of a 2-year-old child with an 8-month history of a battery impacted in the oesophagus but still able to swallow has been reported. This case is of significance as the battery had become implanted into the oesophageal wall and surrounded by granulation so dense that the metallic nature of the foreign body was not identifiable intraoperatively. A decision was made to perform an external approach (right posteriolateral thoracotomy) the following day with success.[119]

Debate surrounds the post-operative management of the patient following pharyngo-oesophagoscopy and battery removal. An initial post-op chest X-ray may identify a pneumothorax (around 0.8%)[15] or pneumomediastinum.[112] Possible options include nasogastric tube, proton pump inhibitors, repeat endoscopy or contrast swallow a few days to a week later.[120] Steroids have not been shown to confer a clinical benefit following caustic ingestion, even though there is a theoretical expectation that fibrosis and stricture formation might be reduced.[121] The placement of a nasogastric (NG) tube serves to allow adequate nutrition and perhaps is a form of stenting. However, the blind placement in a corroded oesophagus may present increased risk.[122]

Nasal button battery foreign bodies have been shown to cause septal ulcerations, septal perforation, inferior turbinate ulceration and necrosis.[123] An external auditory canal button battery foreign body may cause skin ulceration, serosanginous discharge and tympanic membrane perforation.[123]

Magnets have been used to remove metallic nasal foreign bodies.[124] Magnets can be problematic as foreign bodies. The danger arises if either more than one magnet is inserted (e.g. nose or swallowed) or one magnet and another metallic object is inserted. The median number of magnet-associated foreign body incidents was two items. Again, there is a prevalence in boys (63%). Magnetic foreign bodies have a larger median volume compared to non-magnetic foreign bodies.[125] The fashion for magnetic earrings across the nasal alar region has inadvertently resulted in some cases of the magnets being misplaced and attracting across the nasal septum resulting in septal injury and even septal perforation due to pressure necrosis.[126, 127] When swallowed, the same mechanism is responsible for attraction across different regions of intestine, with resultant perforation and death.[125]

Caustic agent ingestion

Caustic ingestion is important in young children as these liquids typically have no flavour or odour. Strong alkalis cause injury by tissue liquefaction and necrosis. Furthermore, thrombosis of the supplying vessels results in reduced blood flow to hamper healing. A significant proportion in older teenagers and adults are due to a suicide attempt.[122] Detergents in the home are regulated by legislation. Since 2013 there has been a voluntary change by industry to prevent infant access to laundry tablets as these are alkaline. Liquitabs (liquid detergent parcels/tablets) are responsible for 1500 incidents each year in the UK.[128] The liquid within these tablets can also be inhaled and cause ocular injury and even death has been reported.[129] Caustic ingestion injury to the oesophagus can be graded 1–4 based on the

depth of injury. A review of caustic injury to children indicates that grade 1 is erythema and oedema, which can be managed conservatively. However, grade 4, which is perforation, has a poor prognosis.[122] Most strictures occur within 8 weeks of caustic ingestion and the subsequent dilatations may result in perforation. Furthermore, the risk of subsequent carcinoma is significantly higher (1000-fold). The carcinoma develops at the site of stricture.[130] For more detail on caustic ingestion, see Chapter 45, Oesophageal disorders.

KEY POINTS

- Foreign body-related incidents are common.
- Battery foreign bodies are increasing in frequency and can be fatal.
- Battery foreign bodies require removal without delay.
- A history of possible foreign body inhalation despite a comfortable patient should prompt bronchoscopy, even when chest examination and X-ray are normal. Neither examination nor plain chest films can exclude foreign body, and the risk of lung damage from an undiagnosed foreign body outweighs the small risk of complications of bronchoscopy in experienced hands.

CHAPTER 35

PAEDIATRIC TRACHEOSTOMY

Michael Saunders

SEARCH STRATEGY

Data in this chapter may be updated by a Medline search using the keywords tracheostomy and child. The author has a personal bibliography of key papers on tracheostomy in children.

INTRODUCTION AND HISTORICAL PERSPECTIVE

Widely acknowledged as one of the oldest documented surgical procedures, detailed historical accounts of tracheostomy are many and vivid. Use of the procedure in children developed in the 19th century after Trousseau used the technique to relieve airway obstruction in diphtheria. Subsequently, the procedure was widely used in the treatment of poliomyelitis. With the introduction of extensive vaccination programmes these diseases have largely disappeared in the Western world.

Until the late 1970s many tracheostomies in children were performed to relieve airway obstruction in acute airway infections such as epiglottitis and acute laryngotracheobronchitis (ALTB, or croup).[1–3] As the standard of paediatric intensive care facilities improved and prolonged endotracheal intubation became a practical alternative to surgical tracheostomy, progressively fewer procedures were carried out for these indications. By the time haemophilus influenza b (Hib) vaccine was introduced in the 1990s, endotracheal intubation rather than tracheostomy had become the accepted mode of airway management for acute bacterial epiglottitis.[4]

In a series of 153 paediatric tracheostomies, Line et al.[2] report that prior to 1980 38% of tracheostomies were performed for acute airway infections whereas after 1980 this figure had dropped to 12%. Similar findings were reported by Friedberg and Morrison[5] when comparing a series of tracheostomies from 1981 to 1985 to a similar series from the same institution from 1976 to 1980. Crysdale et al.[6] also report an overall reduction by half in the incidence of tracheostomy in the same period, attributed to the change in management of epiglottitis. Corbett et al.[7] reviewed 116 cases over a 10-year period (1995–2004) and reported a further shift in indications, with no tracheostomies for acute airway infections alone and an increasing proportion required for congenital defects such as craniofacial anomalies and major upper gastrointestinal defects. Eighteen children (15.5%) required tracheostomy for acquired airway lesions including subglottic stenosis, vocal cord palsy and respiratory papillomatosis, while 14 tracheostomies (12.1%) were to facilitate management of airway malacia (laryngotracheal, bronchial or a combination). Tracheostomy was also required for long-term ventilation in patients with neuromuscular disorders (14; 12.1%) or ventilator dependency (31; 26.7%).

Tracheostomy in children is now an uncommon operation. Due to a shift in tertiary paediatric treatment to larger centres in the last decade and the lack of a reliable means of collecting data on a national basis, it is difficult to estimate the true incidence of paediatric tracheostomy. A survey of 2065 tracheostomies across the United States estimates a rate of 6.6 tracheostomies per 100 000 child years, with the highest incidence in the first year of life

but with a second peak in incidence in the late teens due to increased risk of serious injury and trauma.[8]

A more recent study of indications in 501 tracheostomies between 1984 and 2014 has found that the commonest indications for tracheostomy in children are now cardiopulmonary disease (34%), neurological impairment (32%) and airway obstruction (19%).[9]

As a consequence of the relative scarcity of the procedure, the medical literature relating to paediatric tracheostomy is generally related to level 3 and 4 evidence. There are no significant randomized controlled trials and the majority of publications tend to document the authors' own series of tracheostomies and their complications in larger children's hospitals. Reports of changing indications from such institutions may also be skewed by changes in medical practice in individual units.

INDICATIONS FOR PAEDIATRIC TRACHEOSTOMY

The general indications for tracheostomy are as follows:

- to relieve upper airway obstruction
- to prevent complications of prolonged intubation
- to reduce anatomical dead space
- to allow suction toilet of the trachea.

In practice, tracheostomies in children are nearly always performed to relieve upper airway obstruction or to allow or assist with mechanical ventilation.

Obstruction of the upper airway

The upper airway (from the lips and anterior nares to the carina) may become obstructed at one or more anatomical levels by a range of pathologies (Table 35.1). If the obstruction is significant and life-threatening and no other means of relieving the obstruction (e.g. nasopharyngeal airway or prong) is appropriate, then a tracheostomy must be considered.

Increasing availability and standard of paediatric intensive care facilities has allowed surgical procedures involving the airway to be undertaken without the need for a covering tracheostomy. Instead, the risk of post-operative airway obstruction is avoided by a period of intubation and ventilation (the 'single-stage' approach).

TABLE 35.1 Examples of obstruction of the upper airway potentially requiring tracheostomy

Anatomical site	Example
Oropharynx, tongue base	Macroglossia Treacher Collins/Goldenhar syndrome Cystic hygroma
Nose, nasopharynx	Choanal atresia
Supraglottis	Supraglottic cyst
Glottis	Vocal cord palsy Physical trauma
Subglottis	Subglottic stenosis, haemangioma
Trachea	Tracheomalacia High tracheal stenosis

The relative indications for tracheostomy continue to evolve: until the late 1990s, tracheostomy was considered the mainstay of management for obstructing subglottic haemangioma. Tracheostomy can be avoided using drug treatment[10] or surgical excision[11, 12] Similarly, the introduction of the cricoid split[13] and single-stage laryngotracheal reconstruction[14] has reduced the need for tracheostomy for extubation failure due to subglottic oedema or stenosis.

Prolonged intubation

The long-term complications of prolonged endotracheal intubation are well recognized: ulceration at the level of the glottis and, particularly in children, the subglottis, can lead to cicatrization and stenosis of the airway.[15] Being softer and more flexible than the adult and with correct selection of tube size and appropriate intensive care, the neonatal larynx is able to tolerate prolonged intubation for relatively longer than the adult.

There is no clear consensus as to the maximum safe duration of intubation. Premature babies may now be intubated for several weeks before permanent damage becomes a risk. Although practice varies in different units, tracheostomy should normally be considered in older children after 2–3 weeks of endotracheal intubation.

Long-term and home ventilation

An increasing number of children are now surviving previously lethal conditions, resulting in chronic respiratory failure because of the availability of long-term ventilation, either in a hospital setting or at home. In a 2011 survey of centres offering this service, out of 933 home-ventilated children in the UK, 206 had tracheostomies.[16] Indications for long-term ventilation include:

- congenital central hypoventilation syndrome
- spinal injury
- congenital myopathy
- airway malacia
- chronic lung disease.

Increasingly, these patients can be ventilated at home rather than in hospital although the cost in terms of manpower and equipment is high. The demands placed on the tracheostomy itself are higher and there is a higher risk of tracheostomy-related complications in home-ventilated children.

Tracheal toilet

In practice, very few children now require tracheostomy for toilet of the airway. Children with intractable aspiration may need regular suction but the presence of a tracheostomy can predispose to aspiration in itself and increase the risk of respiratory tract infection.

TECHNIQUES OF TRACHEOSTOMY SPECIFIC TO CHILDREN

Strictly speaking, a **tracheotomy** is the creation of a hole into the trachea. A **tracheostomy** is the fashioning of a permanent opening or stoma between the trachea and the skin. Although this difference has been largely semantic until recent years, it is now an important distinction as surgical technique in children's tracheostomies has evolved.

Positioning

Under general anaesthesia the infant is positioned supine on the operating table. Neck extension is achieved with a rolled towel or gel pillow under the shoulders. The neck can be fixed in extension and stabilized in the midline using adhesive tape such as Elastoplast® (Figure 35.1) or by using a horseshoe-shaped head rest. Theoretically, extension of the neck in infants increases the risk of injury to the great vessels in the root of the anterior neck; in practice, with careful dissection and identification of structures this is rarely a clinical problem. Overextension does, however, risk exposing a significant part of the intrathoracic trachea and can lead to an incision in the trachea which is too low.

Skin incision

In adult practice the conventional skin incision used is horizontal, situated halfway between the cricoid and sternal notch. Traditionally, a vertical incision has been avoided for fear of a poor cosmetic outcome after decannulation. However, after removal of a long-standing tracheostomy, the resulting scar is such that it is unlikely that the orientation of the original incision will make a significant difference. In the last two decades a vertical skin incision has become more popular with specialized paediatric otolaryngologists[17] and is now standard practice in most major children's units (Figure 35.2). A vertical incision has a number of advantages over the horizontal incision: it tends to keep dissection in the midline, reducing a tendency to stray away from the trachea in a difficult dissection, and allows easier placement of maturation sutures. The incision is placed halfway between the cricoid ring and the sternal notch. The skin incision does not need to be a great deal longer than will allow the insertion of the selected tube; surgical retraction of infant skin during surgery tends to lead to the skin defect appearing larger at the end of the procedure than the original incision.

Figure 35.1 Child positioned on the operating table for tracheostomy.

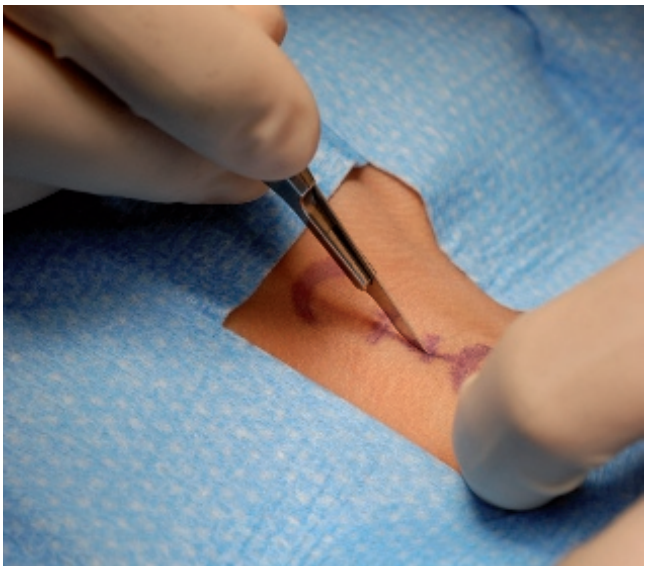

Figure 35.2 Skin incision in paediatric tracheostomy.

Removal of subcutaneous fat and maturation sutures

A disc of subcutaneous fat immediately surrounding the incision should be removed after completing the skin incision. This allows the skin edges to invert slightly so as to create a stoma lined with healthy squamous epithelium. This effect can be increased by suturing the edge of the skin incision to the edge of the tracheal incision (maturation sutures)[18] using absorbable sutures (the author's preference is 4/0 Vicryl Rapide). The resulting opening is more secure and tends to stay open even without the tube *in situ* and is therefore more akin to a surgically fashioned stoma (Figure 35.3) rather than the traditional approach which is essentially an incision in the neck and trachea only held open by the tracheostomy tube itself. Theoretically there is a lower risk of the tracheostomy tube being misdirected into the soft tissues at an emergency post-operative tube change (a false passage).

Stay sutures are placed in the wall of the trachea on either side of the vertical incision. These are generally a removable suture (e.g. 4/0 PROLENE) and are left *in situ* until the first tube change. In the event of accidental decannulation, upward and lateral traction on the sutures will open the tracheostomy to make tube reinsertion simpler. The sutures may be taped to the chest wall (Figure 35.4) to prevent accidental removal.

Figure 35.3 Maturation sutures and stay sutures in a paediatric tracheostomy prior to placement of the tracheostomy tube.

Figure 35.4 Stay sutures taped to the chest wall at the end of the procedure.

Dissection

Dissection using monopolar or bipolar diathermy is advisable in small children to minimize blood loss and should be restricted to the midline to avoid risk to other structures in the neck. Although in adults and larger children the thyroid isthmus is traditionally divided and transfixed to prevent haemorrhage, in infants it is usually adequate to divide the isthmus of the thyroid with bipolar diathermy.

Given the relatively small size of the infant neck and trachea, and secondly the relative proximity of the carotid sheath, it is advisable to palpate the trachea regularly throughout the dissection to ensure that the direction of dissection has not strayed from the midline.

Tracheal incision

A vertical incision is made in the midline, usually in tracheal rings 3–4. It is vital that the cricoid cartilage is identified before the incision is made so that the correct incision can be made. It has long been established that too high an incision in the trachea predisposes to subglottic stenosis.[19] A variety of other incisions has been advocated, including excision of an anterior tracheal window, a superiorly or inferiorly based tracheal flap which is raised and sutured to the skin or, recently, a cruciate incision in the trachea, the tracheal edges being closely apposed to the skin edges.[20] The theoretical advantage of most of these techniques is increased stability of the initial tracheostomy tract and therefore greater safety in the event of accidental decannulation. However, although there is no evidence available from randomized clinical trials, animal experiments[21] suggest that tracheal flaps may lead to an increased risk of long-term stenosis and the majority of authors currently favour a simple vertical incision.

Securing tracheostomy tubes

Until the tracheostome has epithelialized and matured, the risks associated with accidental decannulation are more significant. Initially, it is the author's practice to fix the tube into position in the neck using the inelastic linen tapes supplied with the tube. The tapes are tied in a secure knot, sufficiently tight to allow one finger to be inserted between the tapes and the neck skin (**Figure 35.5**). The tapes should be tightened with the neck flexed, rather than in the operative position with the neck extended. Suturing the flange of the tracheostomy tube to the skin should be avoided in children; infant skin is flexible and thin and does not provide a strong enough anchor point for fixing the tube.

After 7 days the first change is undertaken and the linen tapes may be changed for a Velcro® fastening (**Figure 35.6**) which allows for easier changing and is less traumatic to the skin of the neck. It is vital that, whatever fixing devices are used, they are applied correctly and at the right tension to prevent accidental decannulation.

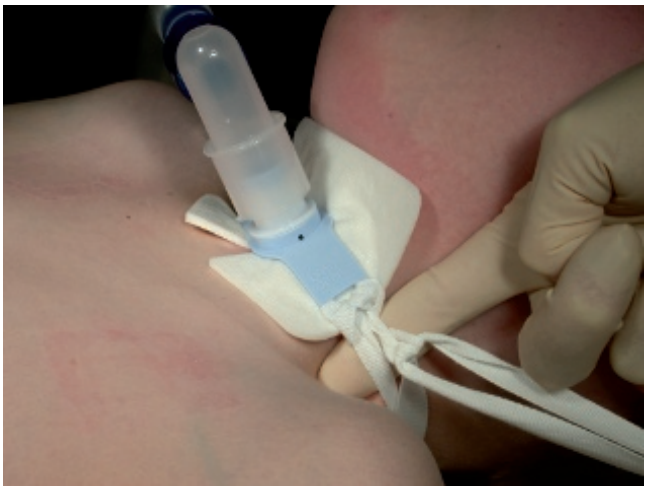

Figure 35.5 Adjusting the correct tension of securing tapes.

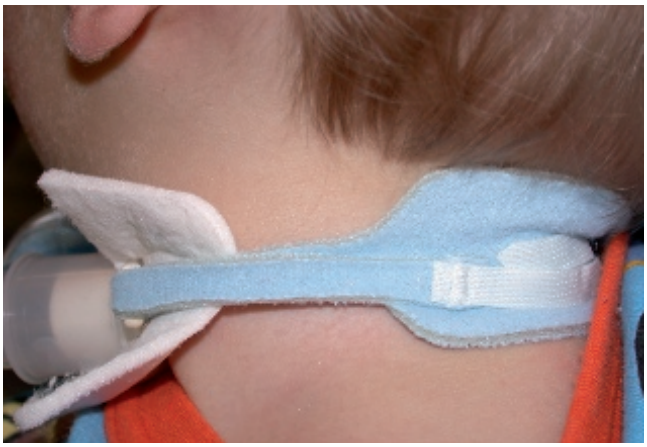

Figure 35.6 Velcro® tracheostomy fitting.

TRACHEOSTOMY CARE

Adequate tracheostomy care is critical in the first 2–3 post-operative days. It is during the formation of the tract of the stoma that the risk of tube displacement is at its highest as initially the tract can close very quickly, making reinsertion difficult. It is difficult to overstate the importance of tracheostomy nursing care in the post-operative period. With meticulous and skilled care, most of the complications of tracheostomy can be avoided. Inexperienced staff with no specific training are often reluctant to intervene. It is therefore essential that hospitals maintain a high standard of internal training in this regard, and many units have specific teams and regular training programmes for nursing staff.

Suction

Immediately after tracheostomy, the change from air that is warmed and humidified by the upper airway to dry, cold air leads to a rapid increase in airway secretions. This gradually reduces after a few weeks. Secretions dry on the inside of the tracheostomy tube and gradually reduce the effective lumen. Humidification of inspired air and regular suctioning will reduce this tendency. Suctioning is required as often as is necessary to keep the tube and airway clear. Overzealous suctioning may lead to mucosal trauma in the distal trachea if the catheter is inserted into the tracheal lumen itself[22] and eventually granulation may form at the tip of the tracheostomy tube, which in itself may lead to tube obstruction. It is suggested that the suction tube be inserted as far as the tip of the tracheostomy tube and withdrawn with a finger occluding the side port. The exact distance may be measured and marked on the suction tube.

The need for suctioning decreases in frequency over time, although with lower respiratory tract infections, secretions may become thicker and more profuse. On such occasions, irrigation of the tracheostomy tube with sterile saline to loosen secretions prior to suctioning is often advocated but there is little evidence to support this practice and it may increase contamination of the lower airway.[23]

Humidification

Initially, humidification should be given via nebulizers and a tracheostomy mask. After a week or so, secretions reduce and the level of humidification required is less. A few weeks after tracheostomy, more mobile devices can replace permanent humidification. Longer-term humidification may be achieved by using a Swedish nose or a tracheostomy bib (Figure 35.7). A heat and moisture exchanger (HME or 'Swedish nose') attachment (Figure 35.8) contains a filter which becomes saturated by the moisture in exhaled air; this in turn humidifies the inhaled air. The tracheal bib works in a similar way. Both devices have the advantage of acting as filters for inspired air.

Skin care

The tracheostomy wound itself becomes rapidly infected with skin commensals and is impossible to keep sterile. The wound heals by secondary intention and eventually the tract becomes lined with squamous epithelium and organized scar tissue. Securing the wound edge skin to the trachea with maturation sutures hastens the development of an epithelialized tract. At this stage the tracheostome is considered mature. Until this point there is usually a considerable discharge from the wound itself and, if the skincare in the first few days is not meticulous, skin and wound breakdown will occur. Usually a dry gauze or foam

Figure 35.7 Tracheostomy bib.

Figure 35.8 Heat and moisture exchanger (HME).

(e.g. Lyofoam®) dressing is inserted between the peritracheostomy skin and the flange of the tube. This is rapidly saturated and needs to be changed regularly. Of course the action of changing the dressing increases the risk of accidental decannulation and there is often reluctance on the part of nursing staff to do this. Adequate training in tracheostomy care is essential in a hospital where regular paediatric airway surgery takes place.

Large skin incisions are generally not required in elective paediatric tracheostomy. If not adequately closed, a large incision will lead to gaping and wound breakdown. It is futile to attempt closure in this instance because of the bacterial colonization of the wound and inevitable infection. Large tracheostomy wounds require careful dressing and packing similar to a healing ulcer, and a range of wound products are available. The wound will eventually close by secondary intention.

The tapes used to secure the tube in place can lead to ulceration of the neck skin if they are left too tight or for too long. Although the linen tapes supplied with tubes are secure, they are inelastic and have a tendency to cut into the skin. Again, meticulous nursing and skin care is vital. The problem can be reduced by tying the tapes inside a sleeve of Tubigrip™ or part of a large plastic (e.g. endotracheal) tube (Figure 35.9). When the tracheostomy matures, wider softer bands with Velcro® fittings may be used and are less traumatic to the neck skin.

Change of tracheostomy tube

The first change of tube is generally undertaken at around the seventh post-operative day. This allows some time for maturation of the stoma but is short enough to reduce the risk of tube obstruction from dried and thickened secretions. The first change should be undertaken by an otolaryngologist; in the relatively rare instance of difficulty reinserting the second tube, an emergency surgical procedure may be required.

If oral intubation is difficult or impossible (e.g. retrognathia, laryngeal stenosis), it is advisable to undertake the first change in the operating theatre in case further surgical intervention is needed. In children who can be easily intubated (including the majority of children tracheostomized for prolonged ventilation), it is more usual to undertake the first change on the intensive care unit, with an intubation trolley and senior ITU medical staff on hand should reinsertion be difficult and re-intubation be required.

If this procedure is uneventful, the nursing staff can carry out subsequent changes. If discharge home is anticipated, the parents must be taught the tube-changing technique in a secure environment.

There is no standard proscribed interval at which tubes should be changed; this varies between children and also in the same child given variation in season and in the health of the lower airway. The tube needs to be changed before dried secretions start to reduce the lumen of the tube. The old tube should be inspected after removal to determine the degree of contamination and this will influence the interval until the next change. If a tube visibly contains dried secretion on external inspection (Figure 35.10), has an audible whistle due to obstruction ('if you can hear a tube, you should change it') or if the suction catheter cannot be passed due to obstruction, then it should be changed. If the suction catheter does not pass freely after changing the tube, the advice of an otolaryngologist should be sought. (The manufacturers recommend that the commonly used Bivona® and Shiley® tubes are changed after a maximum of 28 days although most tubes are changed more frequently than this on clinical grounds.)

TRACHEOSTOMY TUBES

Diameter

Modern tracheostomy tubes are sized in relation to the diameter of the lumen in millimetres and the length of the tube from the skin flange to the tip of the tube. Some older silver tubes still use the French gauge system of sizing. The age-appropriate size for a tracheostomy tube can be derived from the guide shown in Figure 35.11. In general terms, smaller-sized tubes become obstructed more easily

Figure 35.9 Modified endotracheal tube used to protect the neck skin from tracheostomy tapes.

Figure 35.11 Chart for sizing tracheostomy tubes. Reproduced from Tweedie et al.[25]

and may impair respiration if too small for the age of the child. A child with a long-standing tracheostomy should undergo regular age-appropriate 'upsizing'. However, tracheostomy tubes tend to almost completely fill the trachea in very young children, making normal speech difficult. In some cases – for example, if the airway above the tracheostome is not completely obstructed – a smaller-sized tube will allow air to flow up thought the glottis and aid in normal speech production. Too large a tube will predispose to suprastomal collapse and may increase the risk of granulations and stenosis.

Tube length

When inserted correctly, the end of the tracheostomy tube should sit comfortably proximal to the carina. Too long a tube will abut the carina and lead to ventilation problems, mucosal injury and potentially subsequent scarring. Too short a tube increases the risk of accidental decannulation. Ideally, the tube should be at least 2 cm, inside the stoma and 1–2 cm clear of the carina.[24] Tube tip position can be assessed on chest X-ray, at regular rigid bronchoscopy or by passing a flexible endoscope down the lumen of the tube to inspect the carina.

Material

The use of metal and very rigid plastic tracheostomy tubes in children has been largely superceded. Soft or siliconized PVC is now the most widely used material in paediatric tracheostomy tubes and materials may be hydrophobic to reduce the deposition of secretions. The relative flexibility of newer tubes reduces the risk of mucosal trauma during neck movements and the soft flange is less likely to lead to skin injury around the tracheostome. One advantage of metal tubes was that, as the stronger metal wall could be made thinner, it was possible to achieve a larger lumen for the same outside tube diameter and as a result an inner tube could be used. The thickness of the wall of standard tubes makes inner tubes impractical in all but the largest children's tracheostomy tubes.

Fenestration

Fenestrated tubes allow air to pass upwards through the glottis in expiration to improve phonation. These are less practical in smaller children as the fenestration tends to become a focus for granulation and mucosal trauma on suctioning. Adequate passage of air upwards into the larynx is usually achieved by selecting a smaller tube diameter and allowing air leakage around the tube on expiration.

Cuff

There are two specific indications for cuffed tubes in children: first, where there is a significant risk of aspiration (although a cuff will not completely protect against this) and, second, where there is a decrease in lung compliance with intercurrent infection in a ventilated child and ventilation pressures need to be raised temporarily. In this instance, the risk of tension pneumothorax is significantly increased. In the author's institution, children on the home-ventilation programme are admitted to hospital for observation if the ventilation pressures become high enough to require a cuffed tube.

The presence of a cuff increases the risk of mucosal ischaemia and subsequent tracheal stenosis, particularly if high cuff pressures are employed. Traditionally, cuffed tubes are rarely indicated in paediatric practice; until adolescence, a sufficient seal to allow positive pressure ventilation can normally be achieved with an uncuffed tube. In the last decade there has been an increase in the use of cuffed endotracheal and tracheostomy tubes in paediatric intensive care units. This may reflect the increasingly complex nature of children being treated in hospital but it is not currently clear if this will lead to an increase in the rate of subglottic and tracheal stenosis.

Types of tube

An increasingly wide variety of tracheotomy tubes is available for specific indications. An excellent review of available tubes is given by Tweedie et al.[25] The commonest standard tubes used in the UK at the time of writing are the Shiley® and Bivona® tubes. They are available in neonatal and paediatric lengths, and the Shiley® tube is also available in a paediatric long (PDL) size for older children.

The Bivona® Flextend™ tube is a silicone tracheostomy tube with a longer external component than a normal tracheostomy tube (**Figure 35.12**). This allows a greater degree of flexibility in children who are mechanically ventilated and is particularly useful in very small infants with a limited gap between the chin and chest (**Figure 35.13**). The main disadvantage of this tube is the increased length of tube, which increases the dead space and risk of obstruction by secretions.

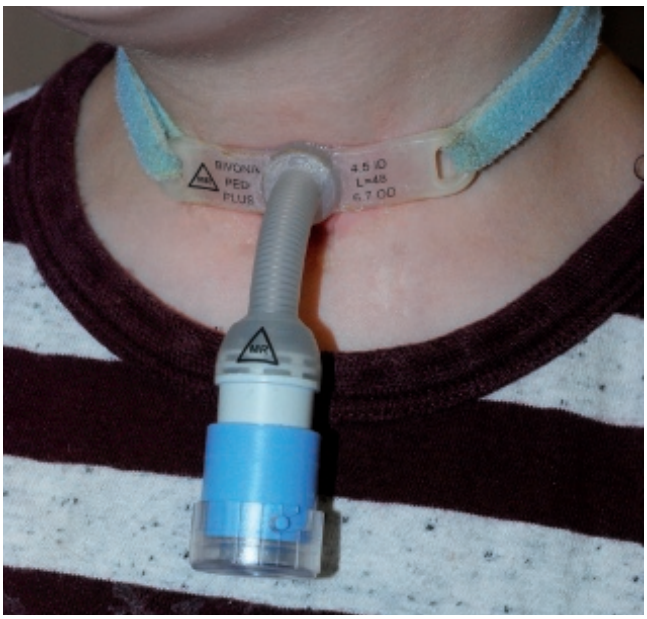

Figure 35.12 Bivona® Flextend™ tube (with Rusch speaking valve).

Figure 35.13 Anatomical difficulty with limited space between the chin and the chest wall.

The Bivona® Hyperflex™ tube has an adjustable flange which allows change of the effective length of the tracheostomy tube (Figure 35.14). This is useful in children with particular anatomical constraints, for example where a low tracheal obstruction needs to be bypassed by the tube and a standard length tube cannot be used. The disadvantages of this sort of tube are that it is expensive and that the wall of the tube is thick, resulting in a relatively small tube lumen. Other custom-made tubes are available for children with specific anatomical difficulties. Tube manufacturers should be approached directly for advice.

Speaking valves

Speaking valves are one-way valves which allow inhalation though the tube but force air upwards through the glottis on exhalation, creating sufficient subglottic pressure to allow phonation. As well as allowing speech, by increasing tracheal pressure on exhalation, these may improve lung function and reduce aspiration.[26] In addition to these possible benefits, it is beneficial to a child to get used to the sensation of expiration through the normal airway, particularly pre-decannulation. Speaking valves should be used under supervision and not while the child is asleep, and they are best used with advice from speech therapy. Small infants will not always tolerate the valve and quickly learn to blow the valve off the tracheotomy by coughing hard. Many children learn to occlude the end of the tube on exhalation by flexing the neck and occluding the end of the tube with the neck skin to achieve the same result to help phonation. Rusch speaking valves (see Figure 35.12) are open apart from in significant expiration whereas the Passy-Muir® valve (Figure 35.15) is designed to be closed apart from in inspiration and encourages use of the normal airway for expiration even in quiet respiration. The Passy-Muir® valve may be modified in children who find it hard to tolerate by drilling small holes to allow some expired air to escape.[27]

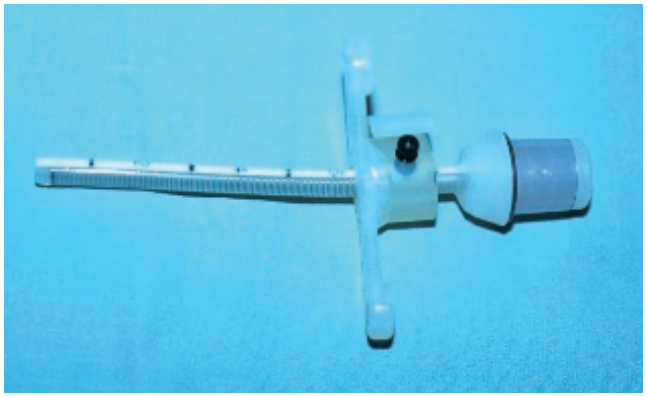

Figure 35.14 Bivona® Hyperflex adjustable tube.

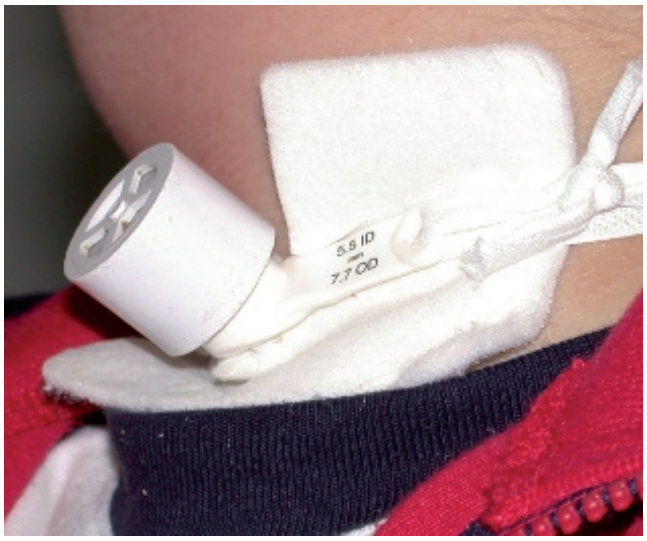

Figure 35.15 Passy-Muir speaking valve.

COMPLICATIONS OF TRACHEOSTOMY

General

Tracheostomy complications are more likely in children than in adults, and more common in children under 2 years of age,[1, 28] particularly preterm infants.[29] Overall complication rates are quoted between 25%[30] and 77%.[31] There is likely to be considerable variation in the documentation and reporting of minor complications – some authors do not consider granulation to be a reportable complication (Table 35.2).

The higher complication rate in smaller children is likely to reflect the relatively small diameter of the airway in small children and the ease with which the airway may be occluded (for example by secretions, granuloma or suprastomal collapse), but also the fact that younger children receiving tracheostomy may remain tracheostomized for a longer period.[31]

As with adult tracheostomies, emergency procedures are associated with a higher rate of complications[32] and longer duration of tracheotomy is associated with a higher risk of long-term complications.[33] Given the relative scarcity of

TABLE 35.2 Complications of tracheostomy

Time after tracheostomy	Complications
General	Tube obstruction Accidental decannulation General complications of surgery and anaesthesia Death
Early post-operative (up to 1 week)	Bleeding: post-operative, wound edge Pneumothorax Subcutaneous emphysema Infection Apnoea
Late post-operative (after 1 week)	Granulation Bleeding Suprastomal collapse Skin complications Aphonia, speech delay Psychological factors Adverse effects on family

paediatric tracheostomy and the limited number of large published series, it is difficult to accurately derive a risk for fatal complications of paediatric tracheostomy. Of larger studies reported since 1980, the mortality related to the tracheostomy tube itself ranges from 0% to 3.6% (Table 35.3).[30, 34] In nearly all cases, the cause of tracheostomy-related death is tube obstruction or accidental decannulation. Earlier reports quote higher mortality rates but paediatric otolaryngology practice has changed considerably in the last 30 years and older studies are unlikely to reflect current practice and safety. Mortality from non tracheostomy-related medical conditions, such as respiratory or cardiovascular disease, is consistently high (7–36%) in all series,[32, 35] reflecting the complex medical conditions of children requiring tracheostomy.

Accidental decannulation

If there is little or no natural airway above the tracheostomy or if a child is ventilator-dependent, accidental decannulation can be fatal. The risk is increased by insufficiently tight ties, too short a tracheostomy tube and excessive traction on the tube from ventilator tubing. In the first few days before the tract matures, it is likely to be harder to reintroduce the tube if decannulated. Wetmore et al.[1] report accidental decannulation in 29 of 420 (6.9%) children in the first week.

The risk of accidental decannulation may be reduced by meticulous tracheostomy nursing care, and surgical techniques (stay sutures, maturation sutures) may help reduce the morbidity by allowing easier and safer reinsertion of a displaced tube. In the event of accidental decannulation, the tube should be reintroduced in a controlled manner to prevent the creation of a false passage.

Tube obstruction

Immediately after tracheostomy the tube is most likely to become blocked with secretions. Regular suction is required. Humidification reduces the rate of secretion and helps to prevent the secretions drying in the lumen of the tube and narrowing the airway. In a mature tracheostomy, the tube is more likely to be obstructed by granulation as

(est) = figure estimated from text.

the tube tip, as a result of either use of suction catheters or direct trauma from the tube itself.

Pneumothorax, pneumomediastinum, surgical emphysema

In the infant the domes of the pleura extend well into the neck. Inadvertently straying from the midline during dissection increases the risk of post-operative pneumothorax. This should be detected immediately post-operatively on a routine chest X-ray. Small pneumothoraces can be treated conservatively while larger ones will require chest drainage.

If the tracheostomy wound is closed too tightly around the tube, or the dressings are too tightly applied to the neck skin, air may leak into the soft tissues of the neck (surgical emphysema) or track down into the mediastinum. In this instance the wound should be reopened to allow air to track back out through the tissues and a corrugated drain should be inserted. Pneumothorax is a rare complication in elective tracheostomy but commoner in emergency tracheostomy.[41, 42] Although it considered normal practice to perform a chest X-ray after all paediatric tracheostomies both to check tube position and to exclude pneumothorax, Genther and Thorne have suggested that the radiation risk from this may not be justified in an otherwise uncomplicated elective procedure.[43]

Bleeding

Bleeding in the first few days after tracheostomy usually arises as a result of failure to achieve complete haemostasis during surgery. Commonly, bleeding may persist from the wound edge, anterior jugular veins or their tributaries, or the edge of the thyroid isthmus. If direct pressure is not adequate to control haemorrhage, the wound may be carefully packed with haemostatic gauze (Surgicel or Kaltostat®). Re-exploration is rarely required.

Later, minor bleeding may arise from areas of granulation around the tube. This can normally be controlled with cautery and ongoing medical treatment such as application of steroid and antibiotic ointment.

Tracheo-innominate fistula

Tracheo-innominate artery fistula is a rare but lethal complication. There is no reliable estimate of the risk in children, which in adults has been estimated as 0.4%.[44]

In some children the innominate artery lies abnormally high in the neck (**Figure 35.16**). If this finding is made at the time of surgery, the decision to perform a tracheostomy should be reconsidered. If there is no safe alternative, it is acceptable to place the tracheal incision higher than one would normally advocate and accept the risk of subglottic stenosis. An abnormally low tracheostomy will also increase the risk. A fistula into the artery forms as a result of erosion of the arterial wall by direct pressure from the tube.

Figure 35.16 High innominate artery.

Although most bleeding coming from the tracheostomy tube itself is likely to represent granulation formation at the tube tip, in all cases the possibility of tracheal innominate artery fistula should be considered. The trachea should be examined by flexible bronchoscopy on the ward or by rigid endoscopy under anaesthesia. If the bleeding appears to arise from the anterior tracheal wall rather than tube-tip granulation, the wound must be re-explored immediately, ideally with the assistance of a cardiothoracic surgeon. It may be possible to tamponade the bleeding by using a cuffed tube temporarily and, if the laryngeal anatomy permits, endotracheal intubation should be established prior to exploration. The mortality from this complication remains very high.

Granulation

The presence of the tracheostomy tube as a foreign body and the persistent presence of bacterial flora in the tract act as an ongoing stimulus for the formation of granulation tissue. Granulation may form at the skin edge of the tract (peristomal granulation) and inside the trachea itself, both on the anterior wall of the trachea above the tube (suprastomal granulation) and also at the tube tip lower in the trachea. Excessive or overexuberant suctioning can lead to more granulation through mucosal trauma and the tube itself can cause mucosal injury. This was generally more common with more rigid tube designs, particularly the silver[45] and PVC designs.

Granulation tissue can pose a number of problems: on the surface, granulations tend to discharge and bleed and, when severe, they can lead to difficulty in changing the tube. More modern tubes made from less reactive silicone are more flexible and softer and are felt to reduce the problem both at the skin and inside the trachea.

Peristomal granulations can generally be controlled with topical steroid/antibiotic preparations. When more severe, they may be removed with bipolar diathermy. Caution needs to be exercised when using silver nitrate cautery as the silver nitrate solution can easily enter the

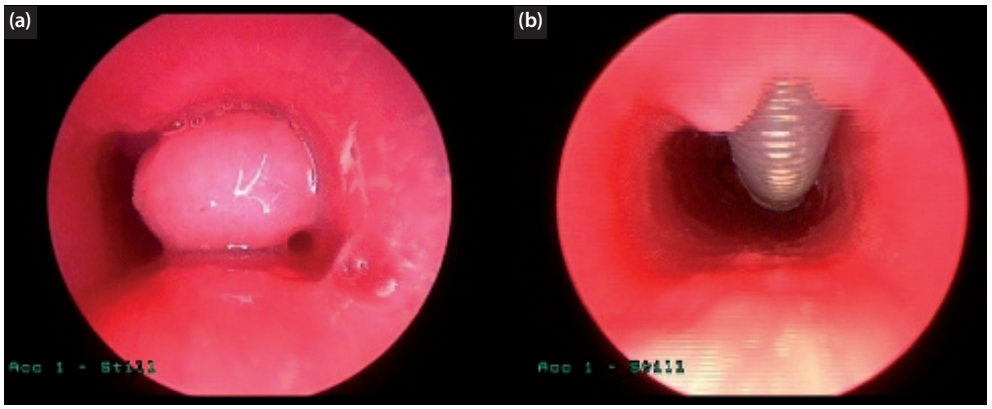

Figure 35.17 Obstructing suprastomal granuloma
(a) before removal, and
(b) 1 month after removal.

trachea itself, leading to irritation, coughing and mucosal injury. In the author's unit, this practice is avoided.

Suprastomal granulations are almost universal. In theory, if they are large, they will reduce the lumen of the supraglottic airway above the tube and increase the risks associated with accidental decannulation. Large suprastomal granulations can affect tube changing and make the use of a speaking valve impossible (**Figure 35.17**). Many authors advocate their removal at endoscopy on a regular basis,[46] however others feel that they are an inevitable consequence of tracheostomy; Rosenfeld and Stool[47] describe granulation in 80% of 265 tracheostomies at bronchoscopy and advise against interval endoscopy to remove granulation tissue. At microlaryngoscopy, immediately prior to planned decannulation, all granulation should be removed to maximize airway patency. After decannulation and stomal closure, granulation generally resolves spontaneously.

REMOVAL OF SUPRASTOMAL GRANULATION

If required, suprastomal granulations may be removed endoscopically using microlaryngeal instruments, a microdebrider using a Skimmer® or Tru-Cut® blade or by KTP or CO_2 laser. The KTP laser has the advantage of beam delivery using a flexible optic fibre in the relatively limited confines of the subglottis.

Large granulation may be removed using a small sphenoid punch or a sinus surgery backbiting forceps inserted into the tracheostome from externally, under endoscopic guidance at mircrolaryngoscopy. Alternatively, if the child can be intubated normally, the ET tube pushes the granulation externally out of the stoma where it can be excised by sharp dissection.[48]

Suprastomal collapse

Suprastomal collapse is distinct from suprastomal granulation although the two conditions often coexist. For reasons that are not completely understood, the anterior tracheal wall immediately superior to the stoma itself softens and prolapses into the lumen of the subglottic trachea (**Figure 35.18**). This can significantly reduce the available airway, which in turn increases the risks associated with accidental decannulation and also leads to decannulation failure.

Figure 35.18 Suprastomal collapse.

Minor collapse may be left, as it will tend to improve after decannulation. More significant collapse will require surgical treatment. The simplest of these involves excision and transfixion of the tracheostomy tract followed by endotracheal intubation for 2–3 days to support the trachea as the stoma heals.[49]

The author's preference in mild to moderate suprastomal collapse is to explore the neck, identify the area of suprastomal collapse and pass a suture through the cartilage and around the strap muscles to elevate the collapsed section. This is carried out with excision and transfixion of the tracheostome skin. Sharp and Hartley[50] describe ablation of the collapsed segment with KTP laser, and a number of authors have described supporting the collapsed segment with a cartilage graft in more severe collapse.[51] The specific procedure will depend on the degree of collapse and the surgeon's personal preference.

Speech development

A tracheostomy may adversely affect the development of speech in children. Clearly, normal phonation will be impaired for the duration of a tracheostomy as insufficient subglottic pressure is generated, and small infants tend not

to tolerate speaking valves well. A significant proportion of tracheostomized children have coexisting developmental abnormalities which can make it difficult to assess the relative effect of the tracheostomy. If decannulation occurs in the first 12–18 months, before the time at which normal speech patterns begin to develop, the long-term outcome is favourable,[52] whereas longer-term tracheostomy may lead to longer-term impairment of speech function.

Effects on caregivers and family

Caring for a child with a tracheostomy puts a significant strain on carers and families. The demands on the caregiver's time may be exhausting and the extra effort required may prevent carers engaging in employment. As a result, mental health status[53] and social-economic status[54] are adversely affected in caregivers of children with tracheostomy. The degree of community nursing support that families currently receive in the UK is very variable and dependent on local healthcare policy and provision.

TRACHEOSTOMY SAFETY INITIATIVES

The majority of life-threatening tracheostomy-specific complications (tube displacement and blockage) should be avoidable with correct tracheostomy care. Furthermore, if these complications are recognized quickly, they should be rapidly treatable. Children with tracheostomies are unusual and the medical and nursing skills required are not always immediately available. The UK National Tracheostomy Safety Project[55] is a multidisciplinary collaboration devised to improve the management of child and adult patients with tracheostomies. The recommendations of the project include the following:

1. An emergency minimum set of equipment should accompany a tracheostomy patient at all times, including spare tubes, suction catheters and dressings (Figure 35.19).

Figure 35.19 Box containing emergency equipment for a tracheostomy patient.

2. Bedhead documentation should be displayed at all times providing immediately visible information including tube size and length, and existing upper airway abnormalities (Figure 35.20).
3. Emergency treatment algorithms should be provided for attending resuscitation teams (Figure 35.21).

It is hoped that making this information and equipment visible to first responders and resuscitation teams will improve the safety of patients with tracheostomies and

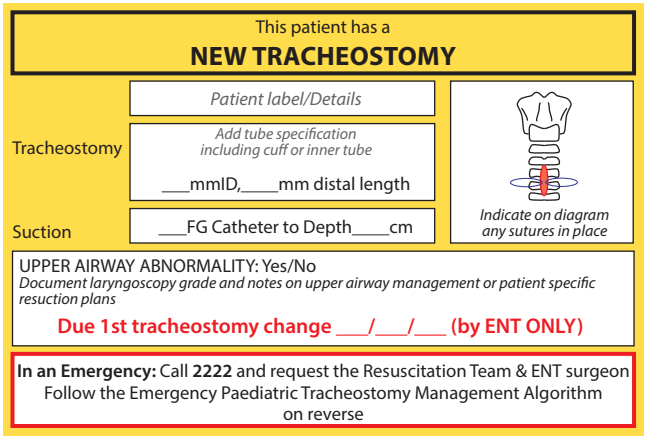

Figure 35.20 Bedhead documentation for a new tracheostomy.

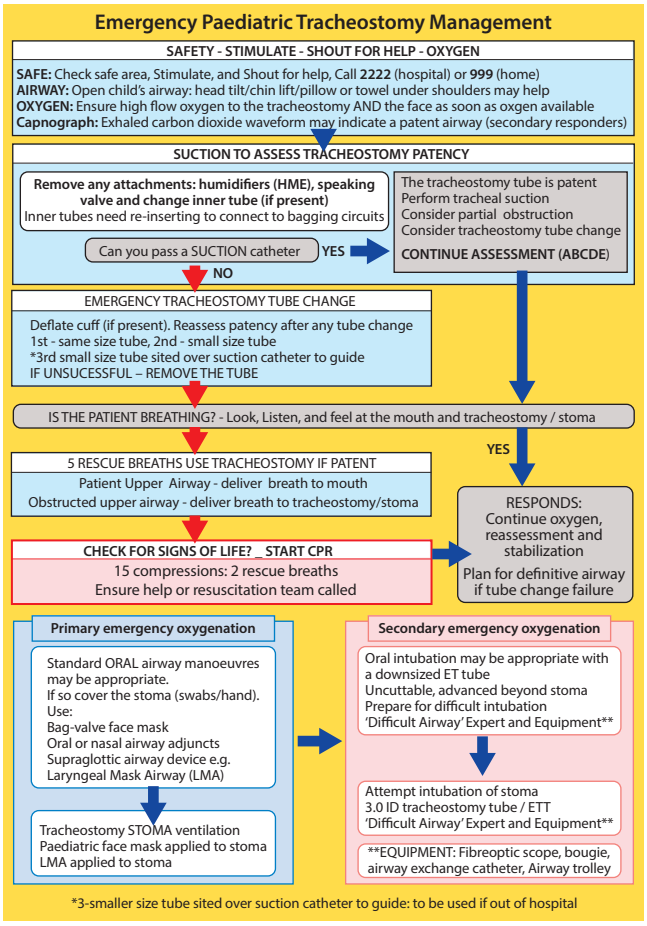

Figure 35.21 Emergency algorithm for resuscitation.

the outcome of complications. The Global Tracheostomy Collaborative formed in 2012 is a multidisciplinary and international organization which shares information and experience to disseminate best practices and improve outcomes.[56]

DISCHARGE AND HOME CARE

Discharge

Getting home with a tracheostomy is a complex and time-consuming process. Not all families will have sufficient support or resources at home to care for children with a tracheostomy. While in hospital, the caregivers must be educated to care for the day-to-day eventualities of tracheostomy, including tube changing, the recognition and initial treatment of complications and basic life-support training.[57] Generally, two responsible adults are required for tube change; home tracheostomy care is difficult but not impossible for single carers. Children who are included in home-ventilation programmes tend to be more carefully supervised and a national protocol for discharge requirements is well established.[58] Non-ventilated tracheostomized children tend to have less structured support. In some areas, specific local organizations exist for the community nursing care of children with complex illnesses; in other areas home care is shared between hospital and primary care district nurses who have little specific training.

With sufficient support and education of teachers and coworkers, tracheostomized children without other significant disabilities can now attend mainstream schooling in the UK, although certain activities must be avoided, particularly swimming, water-based sports and contact sports.

Physical requirements

Boxes 35.1 and 35.2[59] list the resources required for the child with a tracheostomy at home. In the author's experience, the ease with which equipment and accessories can be obtained by caregivers is extremely variable in the

BOX 35.1 Requirements for children at home with tracheostomy

Caregivers	Physical	Support
Generally two responsible adults	Home with adequate space, heating, electricity, telephone, access to transport	District nurse Community paediatrician Health visitor General practitioner Hospital-based support Specific community organizations where available

BOX 35.2 Equipment requirements for children at home with tracheostomy with and without home ventilation

Most of the items need to be duplicated in a portable set. A battery-powered suction machine is essential and, if the child is oxygen-dependent, portable cylinders. Reprinted with permission.[57]

Requirements for children without ventilation	Additional requirements for children on home ventilation
Appropriate-sized tracheostomy tubes and one a size smaller	Two ventilators/CPAP machines, one of which is portable plus batteries and chargers for use outside the home
Neck ties to hold tube in place	Disposable ventilator circuits
Scissors for emergency tube change to cut neck ties	Humidifier for ventilator circuit and water for inhalation to supply humidifier
Lubricant for inserting tube	Dry circuit for ventilation when outside the home
Sterile saline and syringes for saline suction if required	Heat and moisture exchanger for dry circuit
Tracheostomy dressing if required	Nebulizer
Gauze to clean stoma	CO_2 monitor
Appropriate-sized suction catheters	Rechargeable torch for use at night in the event of a power cut
Heat and moisture exchangers / Swedish noses	Uninterrupted power supply – battery which powers ventilator in the event of a power cut
Speaking valves	Suitable trolley in bedroom for equipment
Gloves – non-sterile for procedures and alcohol gel hand rub	Adequate power sockets in house, particularly child's bedroom
Plastic aprons and protective goggles	Trolley for children with a lot of equipment to transport equipment at nursery/school
Stethoscope	Larger than normal buggy when baby/toddler to transport child and equipment
Two suction machines, one of which must be portable. Most children keep a third machine at school as spare	
Saturation monitor and possibly portable saturation monitor for use outside the home	
Ambu bag	
Oxygen: concentrator if used on a daily basis, cylinders if used less frequently, portable cylinders	

community as financial constraints in the delivery of care lead to reluctance to supply regular consumables. Prior to discharge, it is essential to communicate with the child's general practitioner and other primary care workers and establish responsibility for provision of equipment.

DECANNULATION

Decision to decannulate

Decannulation may be considered when the original condition requiring tracheostomy has improved but, to make decannulation successful, the child must be able to maintain an adequate airway without the tracheostomy in place.

The majority of paediatric tracheostomies are short term, as the natural airway tends to improve with overall growth of the child or as a result of corrective surgery such as laryngotracheal reconstruction. The decision to decannulate is a complicated one which needs to be taken by a senior clinician after careful discussion with the parents and other relevant healthcare professionals.

In paediatric otolaryngology practice it is generally considered essential to undertake endoscopic assessment of the airway prior to definitive decannulation.[49] Suprastomal collapse and granulation lead to a considerable reduction in the lumen of the subglottic airway in children. Prescott[60] suggested that this was the most common cause of decannulation failure in children, finding significant granulation in 50 and significant suprastomal collapse in 52 of 300 tracheostomies. In addition, vocal cord mobility should be assessed at endoscopy. Granulation may be removed at the time of endoscopy using punch forceps or laser ablation. More significant suprastomal collapse requires KTP laser ablation or reconstructive surgery using cartilage grafting if the collapse is greater than 50%.[50] If the subglottic airway is deemed satisfactory at endoscopy, the child may then proceed to formal decannulation in the next few days.

One should also consider comorbidity, such as pulmonary, neurological disease, and the need for further surgery; if a child requires operations that may temporarily compromise the airway (e.g. mandibular advancement or cleft palate repair), decannulation should be deferred until these treatments are complete.

Decannulation technique

Removal of a tracheostomy leads to a significant change in the physiology of the upper airway. The dead space is doubled and airway resistance is trebled. With a long-standing tracheostomy, the child may have no memory of mouth and nose breathing and the new sensation may be distressing ('decannulation panic').

STAGED DECANNULATION

To effect these changes more gradually, decannulation protocols have been developed which involve tube 'downsizing' and reversible capping (**Table 35.4**).[61] To assess whether the child can breathe through the normal anatomical airway, the tube is capped off, either with a button, by taping or by inserting the obturator. However, the tracheostomy tube itself occupies a significant fraction of the tracheal lumen and, to try to reduce this effect, the tube size is reduced to a size 3.0 (or size 2.5 in children under 13 months[62]), either in stages or in one step. Leaving the small tube *in situ* allows a certain amount of respiration if required and also prevents the tract from closing down should decannulation fail.

TABLE 35.4 Great Ormond Street protocol for ward decannulation. Reprinted with permission[47]

Day	Procedure
1	Admission, downsize to 3.0 tube
2	Block for 12 hours from 8 a.m. If successful, continue overnight for a further 12 hours
3	Decannulate, occlude stoma with adhesive tape and dressing. Observe on the ward
4	Observe off the ward
5	Discharge

IMMEDIATE DECANNULATION

The tracheostomy tube may occupy as much as half of the lumen of the trachea in an infant. If a child can tolerate this degree of obstruction, the airway after decannulation is likely to be more than sufficient. However, some children will not be able to tolerate this degree of tracheal obstruction. In this instance, it may be considered appropriate to simply remove the whole tube and occlude the stoma with a dressing. However, it is vital that this be carried out in a controlled setting (i.e. intensive care) where facilities for intubation are available should decannulation fail and reinsertion of the tracheostomy not be possible. If the nature of the child's airway obstruction is such that oral intubation is not possible (e.g. some cases of Treacher Collins syndrome), then it is not safe to remove the tube in this manner, and decannulation should be delayed until the child is large enough to tolerate staged decannulation with capping off.

Persistent tracheocutaneous fistula

After decannulation, a fistula may persist between the trachea and skin. This may be small and only lead to problems with discharge of tracheal secretions. A larger fistula may continue to function as an alternative airway.

The incidence of tracheocutaneous fistula (TCF) is between 19% and 42% in various series. Certain factors lead to an increased risk: lower age at initial tracheostomy, duration of tracheostomy and, most importantly, persistent obstruction above the level of the stoma (e.g. inadequate reconstruction of subglottic stenosis). Although it is often felt likely that stomal maturation sutures lead to an increased risk of fistula formation, this has been disproven in larger recent series ($n > 100$).[36, 63]

There is no specific consensus as to how long a persistent TCF should be allowed to close before considering surgery. Most authors would allow 6–12 months before formal closure is attempted.

Closure of TCF

It is essential that the upper airway be reassessed prior to TCF closure to exclude persistent obstruction and tracheal granulation. Some children will still be using the fistula as an accessory airway if the original obstruction is not resolved. The persistence of squamous epithelium lining the tracheostome increases the likelihood of a persistent fistula. Surgically removing the skin lining the tract, or cauterizing the tract using diathermy, coblation or chemicals such as trichloroacetic acid may lead to scarring and satisfactory closure.[64] This has become known as **secondary closure** or closure by secondary intention.

More commonly, the tract of the stoma is dissected down to the level of the trachea and closed with transfixion sutures. This is referred to as **primary closure**. The strap muscles can then be reapposed to each other, which tends to fill in the cosmetic defect left after conventional decannulation. Lastly, the scarred skin surrounding the tracheostome can be excised in a fusiform incision with horizontal skin closure. This leads to a much improved cosmetic result. It is the author's practice to leave a drain in the wound for 24 hours in case of air leak from the closure, which might otherwise lead to surgical emphysema and pneumomediastinum.

Because of the increased risks associated with primary closure, some authors advocate secondary closure as the preferred technique[65] although a recent systematic review found no difference in outcome or complication between the two techniques.[66]

Revision of the tracheostomy scar

Revision of the tracheostomy scar (**Figure 35.22**) usually involves a fusiform horizontal incision to excise the scarred skin of the tracheostome with wide undermining of surrounding skin to assist in primary closure. The strap muscles should be identified and reapposed in the midline to eliminate the defect in the contour of the neck skin. Deep dermal/platysmal sutures are used to support the wound and then the skin edges are closed meticulously. Flexing the neck makes it easier to close a large skin defect.

Figure 35.22 Scar following long-term tracheostomy.

BEST CLINICAL PRACTICE

- ✓ Endotracheal intubation rather than tracheostomy is the accepted mode of management for acute obstructing airway infection in children.
- ✓ Premature babies may be safely intubated for several weeks. Tracheostomy should normally be considered in older children after 2–3 weeks of endotracheal intubation.
- ✓ Large skin incisions are generally not required in paediatric tracheostomy. A vertical skin incision is preferred to a horizontal one.
- ✓ Careful dissection using diathermy is advisable in small children to minimize blood loss.
- ✓ Palpate the trachea regularly throughout the dissection to ensure that you have not strayed from the midline.
- ✓ A simple vertical incision to open the trachea is associated with the lowest risk of long-term complications. Avoid removing any cartilaginous tissue in children.
- ✓ Stay sutures in the wall of the trachea on either side of the vertical incision facilitate reintroduction of the tube in the event of accidental decannulation before a mature track has developed.
- ✓ Maturation sutures securing the edge of the skin incision to the tracheal wall lead to a safer and more secure tracheostomy in the initial post-operative period.
- ✓ In children who are difficult to intubate (e.g. retrognathia, laryngeal stenosis), it is safer to do the first tube change in the operating theatre in case surgical intervention is needed.
- ✓ The small diameter of the child's airway makes suction and humidification especially important as secretions can quickly occlude the airway.
- ✓ Tube obstruction or accidental decannulation may be fatal.
- ✓ An 'inner tube' reduces the diameter of the lumen and is therefore not practical in small children.
- ✓ Fenestrated tubes are impractical in smaller children: the fenestration tends to become a focus for granulation and mucosal trauma on suctioning.
- ✓ Cuffed tubes are rarely needed in children.
- ✓ Speaking valves should be used under supervision and not while the child is asleep.
- ✓ The airway should be thoroughly assessed prior to decannulation.

FUTURE RESEARCH

- Paediatric tracheostomy is now largely undertaken in specialist paediatric units. It is difficult for otolaryngologists in training to get experience in the management of children with tracheostomies outside these centres. This trend is likely to increase.
- Research in paediatric airway disorders is focused on conditions which give rise to the need for tracheostomy, such as laryngotracheal stenosis and major congenital anomalies.
- There is a need to improve training resources and support in primary care and community settings to enable families to look after tracheostomized children at home. The work of national and international organizations is helping to improve tracheostomy care.

KEY POINTS

- Tracheostomies in children are performed in the main to relieve upper airway obstruction or to assist with mechanical ventilation.
- A reduction in the incidence and change in the treatment of infections affecting the airway has led to a gradual change in the indications for tracheostomy. Many are now undertaken to allow prolonged ventilation in children with complex medical problems.
- Tracheostomy in children is now an uncommon operation.
- Tracheostomy technique in children has changed in the last decade. Vertical skin incisions and maturations sutures are now considered standard practice.
- Tracheostomy complications are more likely in children than in adults. Preterm infants are at particular risk.
- Specific medical and nursing skills are essential in postoperative care.
- Suprastomal granulations are almost universal in children.
- Getting home with a tracheostomy is a complex and time-consuming process. Not all families will have sufficient support or resources at home to care for a child with a tracheostomy.

PERINATAL AIRWAY MANAGEMENT

Pensée Wu, May M.C. Yaneza, Haytham Kubba, W. Andrew Clement, and Alan D. Cameron

SEARCH STRATEGY

Data in this chapter may be updated by a PubMed search using the term ex utero intrapartum. Reference lists were reviewed for further articles.

INTRODUCTION

Neonates with potentially fatal airway obstruction can have good outcomes if the abnormality is recognized prenatally and the pregnancy managed by a team with experience in interventional delivery. Prenatal and fetal imaging has improved, which allows for earlier and more detailed analysis of the abnormality and planning of the delivery. Advances in anaesthetic techniques and intervention at delivery improve outcomes and reduce morbidity and mortality in this group of patients.

This chapter summarizes developments in imaging, anaesthesia and delivery techniques for neonates with airway obstruction.

PRENATAL AND FETAL IMAGING

A potentially fatal airway obstruction in the fetus can be recognized at prenatal imaging, often initially identified at the routine 20-week ultrasound as part of the fetal anomaly screening programme.[1] Once a neck anomaly has been established, the remainder of the fetal survey is carefully conducted to detect the presence of any other abnormalities. Further information may be gathered via three-dimensional (3D) and four-dimensional (4D) ultrasound or magnetic resonance imaging (MRI), such as fetal swallowing, lung function and neck mass mapping, including the presence of calcifications.[2] Ultrasound modalities are more widely available than fetal MRI, which is currently offered in tertiary centres only. A detailed plan for delivery can then be made as well as preparation for postnatal management.[3]

A fetal neck mass may also present via a fetal growth scan requested due to suspected macrosomic (excessive birth weight) fetus and polyhydramnios (excess amniotic fluid in the amniotic sac) is discovered instead. A large neck lesion may compress the oesophagus and impede fetal swallowing, therefore leading to increased liquor volume, uterine irritability, and threatened preterm labour.

After diagnosis, the pregnancy is closely monitored with regular sonograms, in order to detect any development or worsening of fetal hydrops (accumulation of fetal fluid) – a sign of cardiac failure. Elective delivery with *ex utero* intrapartum treatment (EXIT) is planned if there are markers of hydrops or when the fetus is deemed mature.[4]

Ultrasound

Ultrasound is the mainstay of prenatal imaging as it is deemed safe for the fetus and the mother with prudent use. 3D scanning provides a reconstructed 3D volume

image of the fetus, whereas 4D ultrasound allows a 3D picture in real time showing fetal movements.

In addition to antenatal diagnosis of fetal neck anomalies, pre-operative ultrasound can be used to determine fetal position, mass location and placental site prior to an EXIT procedure.[2] In the case of a large cystic neck mass which may contribute to a difficult and traumatic delivery of the fetal head, ultrasound-guided percutaneous aspiration of the cystic mass can be performed prior to the EXIT procedure.

MRI

An adjunct tool to ultrasound is MRI (**Figure 36.1**). It has superior soft-tissue delineation and anatomical detail (i.e. assessment of tracheal distortion, compression and position). It has better differentiation between solid and cystic structures.[2] Furthermore, when using MRI, there is less adverse influence of raised body mass index, poor fetal positioning and oligohydramnios compared with ultrasound. As measurements can be made of fetal facial features and skeletal angles, syndromes and intracranial anomalies may be more easily identified on MRI.[5]

Static images of the whole fetus can be examined at MRI, therefore a more global view of the mass can be obtained and its spatial relationship to the airway more easily appreciated, in particular using the multiplanar function.[6] It has been suggested that ultrafast MRI without fetal sedation can provide a more comprehensive view regarding the size and position of the lesion.[7] In 50% of cases the MRI finding was different from the ultrasound diagnosis, however the MRI diagnosis was in agreement with final histology in 73% of cases.[8]

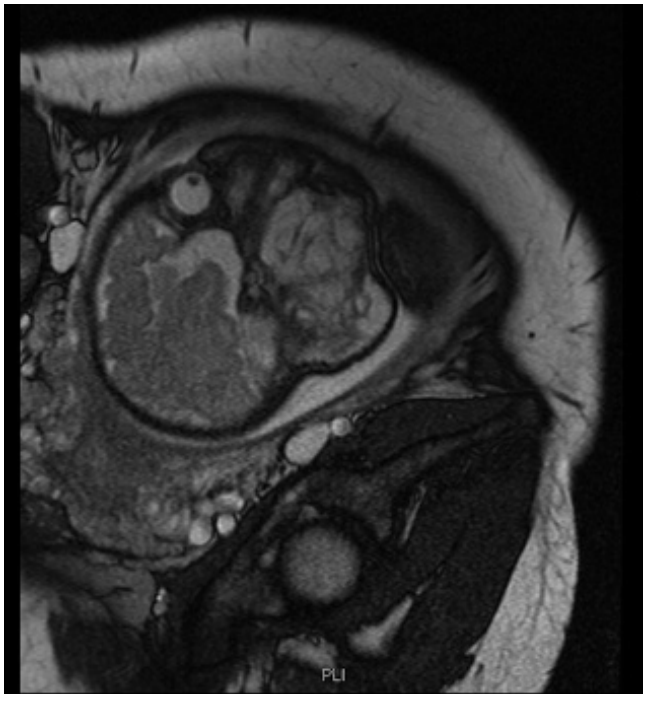

Figure 36.1 Fetal MRI. A large lymphatic malformation (*) is demonstrated.

EPIDEMIOLOGY

The most common fetal neck lesions causing airway obstruction are lymphatic malformations (formerly cystic hygroma) and teratoma. Other neck masses include haemangioma, branchial cleft cyst, cervical thymic cysts, fetal goitre, sarcoma, neuroblastoma, and kaposiform haemangioendotheliomas (**Box 36.1**).[9, 10]

BOX 36.1 Causes of congenital airway obstruction

External compression	Internal blockage	Developmental
Lymphatic malformation	Laryngeal web	Laryngeal atresia
Cervical teratoma	Laryngeal stenosis	Tracheal atresia
Brachial cleft cyst	Laryngeal cyst	Micrognathia
Cervical thymic cyst	Tracheal stenosis	
Thyroid goitre	Epignathus	
Ectopic thyroid	Choristoma	
Sarcoma	Glioma	
Neuroblastoma	Encephalocoele	
Dermoid cyst	Choristoma	
Granular cell tumour	Haemangiomata	
Vascular ring		

Cervical lymphatic malformations are typically located in the anterior and posterior triangles of the neck and appear sonographically as fluid-filled cysts with fine septae. Conversely, cervical teratomas are unilateral and asymmetrically located. They are characterized as complex masses with mainly solid components and well-defined edges, often with vascular spaces and calcifications.[11] Preterm labour from polyhydramnios due to local mass effect causing obstruction in the tracheo-oesophageal complex which leads to impaired fetal swallowing is more common in teratomas (up to 40%) than lymphatic malformations.[12] **[Level 1 evidence]**

Extrinsic compression of the fetal airway

LYMPHATIC MALFORMATION

The incidence of lymphatic malformation is 1 in 6000 to 1 in 16 000 live births. This congenital malformation of the lymphatic system is thought to be due to failure of the jugular lymph sacs to join the lymphatic system. As well as an association with chromosomal abnormalities in 60% of cases, in particular Turner syndrome and Down syndrome, they are also linked to underlying genetic conditions, such as Noonan syndrome and multiple pterygium syndrome.[2] Antenatal care therefore involves detection of other fetal structural anomalies, especially cardiac abnormalities, and the offer of prenatal karyotyping. There is a perinatal mortality rate of over 80% if fetal hydrops is detected. Postnatal intubation may be particularly difficult due to obstruction of the pharynx and larynx from very large lesions. Prognostic scores

such as de Serres staging or Cologne Disease Score have been used to predict long-term outcome.[13, 14]

CERVICAL TERATOMA

Teratomas contain tissue from all three germinal layers (ectoderm, mesoderm and endoderm). Cervical teratomas represent 3–5% of all teratomas and have an incidence of 1 in 35 000 to 1 in 20 000 live births.[15] Cervical teratomas cause airway obstruction via both compressive and distortive factors. A presumed prenatal diagnosis of teratoma is an indication for an interventional birth procedure. It is associated with lung hypoplasia and a higher mortality rate.[16]

Maternal serum alpha fetoprotein (AFP) levels may be very high as these tumours contain neural tissues as the predominant histological component. Only <5% undergo malignant transformation, which occurs in those who are diagnosed in later life. By undergoing EXIT procedure, the neonatal mortality rate is improved to 36% from 80% in those with untreated cervical teratomas.[16]

Intrinsic defects in the fetal airway

CONGENITAL HIGH AIRWAY OBSTRUCTION SYNDROME

There are several causes of congenital high airway obstruction syndrome (CHAOS); these include laryngeal web, laryngeal stenosis, laryngeal atresia, laryngeal cyst, tracheal stenosis and tracheal atresia. Antenatal imaging shows large echogenic lungs, dilated tracheobronchial trees and flattened or inverted hemidiaphragms. Fetal hydrops can develop from reduction in venous return due to compression of the lungs on mediastinal structures.[17] Extrinsic airway obstruction by vascular rings, such as right aortic arch with aberrant left subclavian artery or double aortic arch, can mimic CHAOS.

There is a low risk of future pregnancies being affected as most CHAOS occurs sporadically. However, laryngeal atresia is associated with other anomalies such as anophthalmia, hydrocephalus, syndactyly, absent radius, bronchotracheal fistula, oesophageal atresia, cardiac anomalies, Fraser syndrome, genitourinary anomalies, imperforate anus, uterine and vertebral anomalies.[4] Compared with laryngeal atresia, low thoracic tracheal obstruction or tracheal atresia has a much poorer prognosis for EXIT procedure.[18] It is difficult to diagnose laryngeal atresia on prenatal ultrasound in the presence of a tracheoesophageal fistula as the lung fluid can escape into the stomach or amniotic sac, rather than being trapped in the lungs.

Micrognathia

At the 20-week fetal anomaly ultrasound scan, fetal features of small chin, prominent upper lip or polyhydramnios may raise the suspicion of micrognathia. Fetal MRI can be used to further assess the severity of micrognathia by evaluating the relationship of the tongue to the airway (glossoptosis). Several congenital syndromes are associated with micrognathia, including Cornelia de Lange, Treacher Collins, Marshall syndrome, Stickler syndrome, the Robin sequence and 22q11 deletion.[3]

Oronasal masses

Fetal nasal masses amenable to prenatal ultrasound diagnosis include congenital midline nasal masses, such as dermoids, gliomas and encephalocoeles (extranasal or intranasal), and abnormal nasal anatomy seen in 22q11 deletion syndromes. In the case of fetal oral masses, congenital epulis (granular cell tumours), epignathi (teratoma of the oropharynx) and dermoid cysts of the floor of mouth or tongue base may be detected.[12, 19, 20]

INTERVENTIONAL DELIVERY

The concept of accessing the fetal airway in an elective, controlled and secure manner under placental support was first developed in 1990. The fetus underwent laryngoscopy and intubation prior to clamping the umbilical cord.[21] Previously, an ENT team would be on 'standby' to establish the airway in the neonate under time pressure.

There are currently a number of options for interventional delivery:

- operation on placental support (OOPS)
- *ex utero* intrapartum treatment (EXIT) procedure
- delivery then attempted airway intubation or tracheostomy.

Operation on placental support

Operation on placental support (OOPS) delivery is performed under maternal regional anaesthesia with the fetus completely delivered through a lower segment Caesarean section. The umbilical cord is unclamped and kept intact with the fetus on a Mayo table at the level of the placenta. In order to prolong the foetoplacental circulation, synthetic oxytocin administration to deliver the placenta is delayed. A window of 5–20 minutes for airway intervention has been documented before the umbilical cord goes into spasm.[22]

Ex utero intrapartum treatment (EXIT) procedure

The EXIT procedure has become the mainstay in the management of prenatally diagnosed fetal airway obstruction. Its initial indication was to manage fetuses with congenital diaphragmatic hernias who underwent *in utero* foetoscopic tracheal occlusion to increase lung growth.[23] An EXIT procedure to deliver a fetus with an airway-obstructing neck mass reduces the mortality rate from 10–57% to 8%.[24]

An EXIT procedure permits a longer interventional procedure as the neonate is only partially delivered. Via a lower segment Caesarean section the head and perhaps a shoulder are delivered to maintain uterine volume

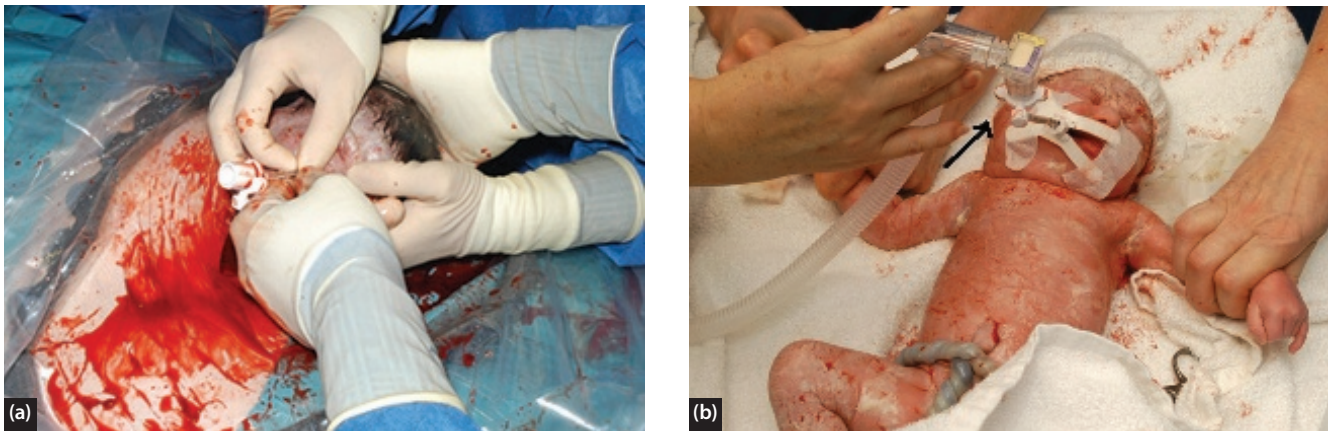

Figure 36.2 EXIT procedure. (a) Head of neonate delivered via lower segment Caesarean section and child intubated. The underlying abnormality was a large lymphatic malformation (fetal MRI of same child in Figure 36.1). **(b)** Intubated neonate with large lymphatic malformation (arrow) assessed by paediatricians.

which in turn avoids compression of the umbilical cord, and allows preservation of the uteroplacental circulation (**Figure 36.2**). A 2.5-hour timeframe is afforded on this circulation to perform airway interventions.[4] These include establishing an airway, direct laryngoscopy and bronchoscopy, performing a tracheostomy, surfactant administration, and resection of an obstructing mass. There is a greater chance of maternal haemorrhage due to uterine atony in an EXIT procedure compared with OOPS (**Table 36.1**).[25] Moreover, it may be difficult to perform fetal intubation and bronchoscopy with only the head delivered. Nevertheless, this procedure can be easily converted to an OOPS. Classically, an EXIT procedure is performed under maternal general anaesthesia[26] but it can also be performed under a spinal anaesthetic.[27]

Delivery then attempted airway intubation or tracheostomy

In certain circumstances, the risk of maternal haemorrhage is severe and a rapid, safe delivery of the baby and the placenta takes precedence. For example, in a mother with uterine fibroids and a fetus with other severe fetal anomalies,[10] a Caesarean section could be performed with the paediatric airway team in attendance to secure the neonatal airway by means of either rigid bronchoscopy and intubation or tracheostomy.

TABLE 36.1 Differences between EXIT and OOPS

	EXIT	OOPS
Anaesthetic	Traditionally uses inhalational general anaesthetic, hence greater risk of maternal haemorrhage Regional anaesthetic can be used	Regional anaesthetic or short general anaesthetic
After uterotomy	Partial delivery of fetal head and shoulders	Whole baby delivered onto Mayo table Umbilical cord left intact Placenta not delivered
Time for interventional procedures	20–50 minutes	5–20 minutes

PRE-OPERATIVE PLANNING

A multidisciplinary team (MDT) is involved in planning the procedure. The pre-EXIT rehearsal would consider the layout of the operating theatre and the location of the personnel and equipment. There should be a clear documentation of the prenatal counselling and consent, including a frank discussion of the options available and a realistic outlook for neonatal survival.[25]

Multidisciplinary team

Prenatal genetic counselling is invaluable in evaluating for underlying genetic syndromes based on the information available during pregnancy, such as fetal karyotype or other structural anomalies detected on antenatal imaging. The parents can then have an informed discussion on whether an interventional birth procedure is suitable for their baby in light of the probable prognosis. Neonates with an isolated airway obstruction (i.e. no other fetal abnormality) have a good prognosis and limited morbidity if delivered by a team with experience in interventional airway deliveries.[27] The prognosis is less good if multiple fetal abnormalities or lung hypoplasia is present.[27] Isolated cervical teratomas also have worse outcomes than compressible neck masses such as lymphatic malformations.

An MDT approach is essential for setting up an interventional airway delivery service (**Figure 36.3**). The team should include specialists from fetal medicine, otolaryngology, neonatology, paediatrics, paediatric anaesthesia and obstetric anaesthesia. Prior to meeting the parents the MDT meets to develop the birth plan. The following

factors need to be considered when contemplating an interventional delivery:

- **Maternal factors:** comorbidities, risk of maternal haemorrhage (i.e. coexisting uterine pathology such as uterine fibroids)
- **Fetal factors:** suspected pathology (i.e. isolated neck mass causing airway obstruction, other fetal abnormalities, lung hypoplasia), gestational age
- **Anaesthetic factors:** this will be determined by risk to maternal health and anticipated length of time required to intervene to secure the neonatal airway
- **Access factors:** presentation of the fetus (breech, head first), size of mass, accessibility for OOPS, EXIT or other intervention
- **Timing of intervention:** an elective lower segment Caesarean section is planned at a gestation guided by the volume of amniotic fluid and the gestational age of the fetus
- **Primary intubator:** the person whose prime responsibility is to intubate the neonate
- **Time allowed for intubation:** this will be determined by the interventional procedure performed, i.e. OOPS or EXIT.

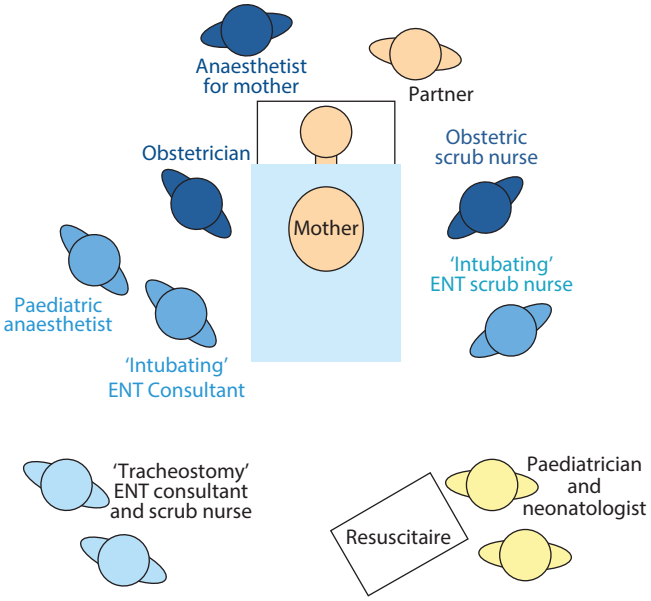

Figure 36.4 Example of theatre layout for an interventional delivery procedure (from Yaneza et al).[27]

A unit that undertakes interventional airway deliveries should be supported by an established framework, i.e. paediatric and neonatal intensive care, extracorporeal membrane oxygenation service, etc. A contingency plan is also developed at the MDT meeting should the mother present in spontaneous labour before her planned date of delivery with the availability and awareness of the on-call MDT able to conduct an emergency Caesarean section and EXIT or OOPS procedure. Extracorporeal life support to provide respiratory support may be considered in neonates with difficult access to airway but a good prognosis, such as a large vascular mass requiring resection followed by a tracheostomy.[25] Due to the number of team members involved, a large operating theatre is preferable (Figure 36.4).

Airway intervention

After the fetal head is delivered, the fetal medicine surgeon ensures maternal wellbeing and prevents placental separation, while the airway surgeon works simultaneously (Figure 36.5). The presence of two ENT consultants is recommended: an 'intubating' ENT consultant with rigid bronchoscopy skills (Figures 36.5b and c), and a 'tracheostomy' ENT consultant. In the event of a failed intubation, the other 'tracheostomy' ENT consultant and scrub nurse can perform a tracheostomy with fresh minds that are not adversely affected by the previous incident. Furthermore, having two ENT consultants allows for a consensus to be reached if a stressful or difficult situation is encountered. The primary intubator could also be a paediatric anaesthetist who specializes in ENT and thus is experienced at managing difficult airways.

Timing

In choosing the gestation for Caesarean section, the balance between early operation to avoid spontaneous labour and delayed delivery to improve fetal maturity

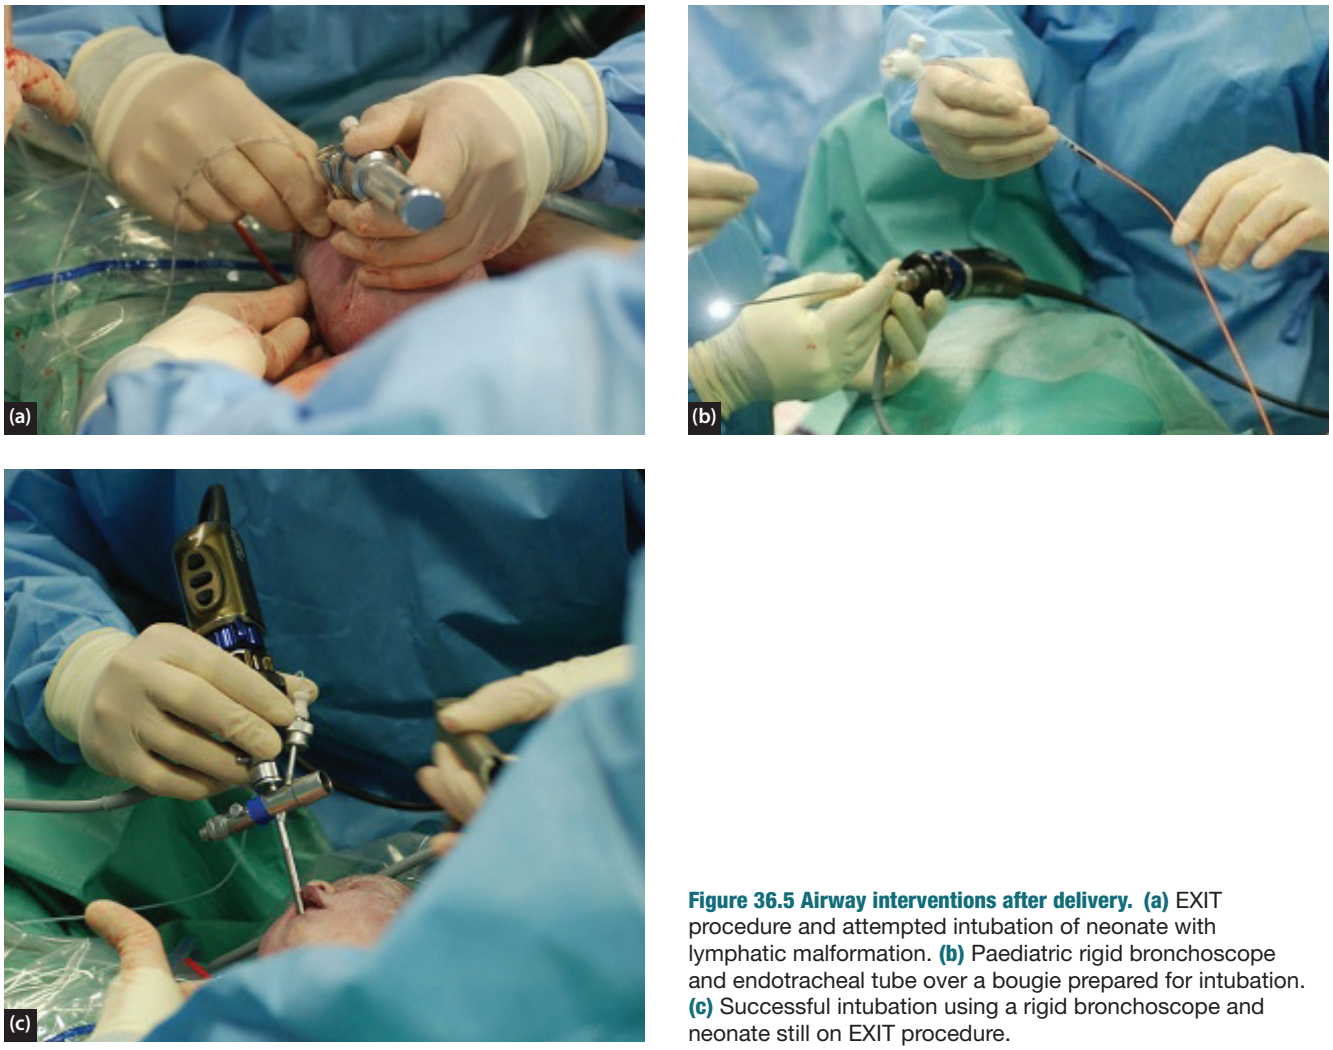

Figure 36.5 Airway interventions after delivery. **(a)** EXIT procedure and attempted intubation of neonate with lymphatic malformation. **(b)** Paediatric rigid bronchoscope and endotracheal tube over a bougie prepared for intubation. **(c)** Successful intubation using a rigid bronchoscope and neonate still on EXIT procedure.

is considered. In many cases, a Caesarean delivery is planned around 36–38 weeks' gestation, after corticosteroid administration to promote fetal lung maturation. However, the delivery may be expedited in the presence of polyhydramnios as the risk of preterm labour increases with the volume of amniotic fluid.[26]

Anaesthesia

A Caesarean section is usually performed using regional anaesthesia, i.e. spinal or epidural anaesthesia. An OOPS procedure can be performed on regional anaesthesia while an EXIT procedure is classically conducted under general anaesthesia to achieve uterine relaxation with a deep plane of anaesthesia. The mother is kept in a left lateral tilt position to avoid aortocaval compression from the gravid uterus, which reduces maternal cardiac output. EXIT procedures have been conducted under regional anaesthesia by the combined spinal epidural technique, with adequate uterine relaxation.[27–29] Agents such as glyceryltrinitrate can be used to induce further uterine relaxation if required.

Two anaesthetists should be present at an interventional airway delivery: an obstetric anaethetist for the mother, and a paediatric anaethetist for the neonate. Despite the intention to have two healthy patients by the end of the procedure, if any conflicts of interest arise intraoperatively, the mother's safety should override any fetal concerns.

During EXIT procedure, uterine relaxation is paramount as the uteroplacental circulation supplies oxygen and anaesthesia to the fetus. The preservation of maternal-fetal gaseous exchange at the placenta prevents fetal hypoxia and neonatal hypoxic-ischaemic encephalopathy. All volatile anaesthetics cross the placenta and fetal anaesthesia is related to uterine blood flow, drug solubility and distribution in the fetal blood circulation.[30] Narcotics or muscle relaxants can be administered to the fetus via intramuscular or intravenous routes to achieve additional anaesthesia.

Obstetric issues

At an elective Caesarean section, the average maternal blood loss is 500 mL,[31] whereas for an EXIT procedure it is 1500–1800 mL.[24] Haemorrhage can occur from the uterine incision, the placenta (premature placental separation) or from an atonic uterus once the baby is delivered.[7]

Bleeding from the uterotomy can be reduced with surgical haemostatic techniques including the placement of a uterine stapling device. Placental damage from the uterine incision should be prevented by mapping the placental edges on antenatal ultrasound and planning the uterine incision. However, a large neck mass may obscure the placenta at ultrasound. One should also exercise caution in the setting of polyhydramnios as the placenta can be compressed and give a false impression of its location on the antenatal scan. Furthermore, upon uterine incision, the sudden release of high volumes of amniotic fluid can lead to intrauterine pressure changes and early placental separation (i.e. placental abruption). Therefore, amnioreduction should be considered prior to EXIT procedure in such cases.
